

Dedication

I dedicate this work to everyone that stood by me during my journey. First of all, to my dearest parents **Souheil** and **Ameni** whose love and guidance nurtured me and paved the way for me in every step of my life. I never underestimated the sacrifices you did for our little family. This achievement, as well as others, is a coronation of your efforts. Beautiful days are coming!

To my brother **Manef**, the source of joy and happiness in our family. Thank you for being who you are, for loving and caring for me in your own way.

To all my family members that encourage me and celebrate me like a kid of their own.

To **Amine**, my support system since day one. Thank you for believing in me and pushing me beyond the limits. Our collaborations and ambitions shall continue. Let's keep dreaming.

To my second family, **IEEE RAS INSAT**: the mentors and the work buddies. I learned a lot from the experiences and from every one there and in particular through the **EUROBOT2023** experience.

To all those who have supported and believed in me, both near and far. Thank you.

Acknowledgement

I would like to express my heartfelt gratitude to all the individuals who contributed to the success of this work through their invaluable feedback, support, and guidance.

I extend my sincere thanks to Prof. **Feiza GHEZAIEL**, the jury president, as well as Prof. **Sonia HAJRI**, the reviewer of this graduation project, for their insightful comments, constructive feedback, and the generous time they dedicated to evaluating my work. Their contributions have greatly enhanced the quality of this study and will continue to influence its future.

I am deeply grateful to my mentor and supervisor, Mr. Dr. **Tino KRÜGER-BASJMELEH**, for his unwavering support, expert guidance, and profound knowledge throughout the course of my research. His wisdom and advice played a crucial role in steering this work to success, and I have learned immensely from him.

My profound appreciation goes to Prof. **Afef BEN ABDELGHANI**, whose expertise and insightful discussions have significantly enriched this research. Her guidance has been a constant source of inspiration, not only throughout this project but since my earliest days at **INSAT**.

I would also like to express my gratitude to my institute, **INSAT**, for the immense impact it has had on both my personal and professional development. The experiences I gained and the people I met there have shaped me as both a person and an engineer.

I acknowledge with sincere thanks all my professors and teachers, whose efforts and dedication were essential pillars in my academic journey, contributing profoundly to my knowledge and growth.

Special thanks go to my esteemed colleagues at **STILL** for their continuous support and cooperation throughout the different phases of this work. I would particularly like to thank **Felix HESS**, **Kevin VORWERK**, **Matthias HAASE**, and **Martin KRIMM** for their valuable advice, as well as **Thomas WITTMANN** and **Volker VIERECK** for generously sharing their expertise.

The steadfast support and belief in my abilities from these individuals have profoundly influenced the outcome of this graduation project. I am truly thankful for their presence and encouragement throughout my academic and professional journey.

Abstract

This thesis proposes a methodology for automated path planning for mobile robots in intralogistics environments, taking into consideration environmental obstacles. The proposed path should optimally connect the robot to a nearby target pose, while adhering to the robot's kinematic constraints. The path planning process should employ an online pattern-based approach, ensuring that the robot's behaviour is explainable, and all environmental recognition information is utilized during path planning. The thesis aims to reduce the amount of information required for commissioning mobile robots, allowing for broader use cases. The proposed solution will be implemented in the Robotics Application Construction Kit (RACK) framework and evaluated for performance in real-time processing capabilities. The thesis consists of literature review, design and development of the proposed solution, and validation through testing in a simple test environment. The proposed methodology will enable mobile robots to navigate intralogistics environments more efficiently and safely, contributing to increased productivity and dynamic logistics processes.

General Introduction

The latest events of the current decade have highlighted the challenges that manufacturers, suppliers, and end customers face during fluctuations in logistics and supply chain processes. Living in a VUCA world—Volatile, Uncertain, Complex, and Ambiguous—requires us to continuously adapt to changes and anticipate future events by preparing our developed environments and scaling our solutions. Simultaneously, it is crucial to maintain high standards that ensure productivity, enhance work safety, and optimize ergonomics.

In this context, the primary objective of intralogistics is to optimize, integrate, automate, and manage internal logistical flows of material and information within distribution centers, warehouses, or manufacturing plants. This subfield focuses on increasing operational efficiency by employing new technologies, such as autonomous robots.

Modernizing industrial environments through intralogistics offers significant potential for companies that adopt and adapt to it. However, convincing potential customers of the efficiency and impact of intralogistics robots presents challenges. These limitations include high training and implementation costs, changes to work routines, and the need for space and process adaptations.

A recent study from CBRE, the world's largest real estate services provider, revealed that European industrial and logistics investments increased by 16% in Q1 of 2024 compared to Q1 of 2023. Despite this, many warehouses are old, repurposed buildings that are unorganized due to the nature of their daily tasks. These brownfield warehouses are expensive to maintain and digitalize but represent ideal grounds for developing and utilizing fully autonomous systems. Unlike AGVs, autonomous vehicles possess the intelligence and capability to plan and execute their plans efficiently. They are designed to adapt to uneven terrains and unorganized working environments given the revolutionary technologies that they hold.

In this context, STILL, a KION group company, has been developing smart intralogistics solutions since its establishment more than a 100 years ago, successfully integrating automation into logistics. STILL offers a wide variety of products that cater to industries ranging from food retail to automotive manufacturing and chemical sectors. Their solutions address various customer challenges, such as

reaching high shelves, order picking, palletizing, fleet management, and providing consulting services. Trusted by leading German companies like Siemens, STILL's products and services are renowned for their reliability and efficiency. The STILL Autonomous Robots department focuses on developing and enhancing smart vehicles. These autonomous robots, with minimal cost-effective input from the warehouse environment, can perceive their surroundings, estimating their positions, efficiently planning future tasks, controlling their movements to reach destinations, executing desired actions, and making corrections if necessary. This focus on smart, autonomous vehicles demonstrates STILL's commitment to pushing the boundaries of intralogistics and automation.

In light of this, this thesis aims to contribute to the process of palletizing by optimizing a local path planning approach applied in the warehouse's stations near the shelves or spots where pallets are located for picking or in free placing areas. The developed approach seeks to plan the near-field path optimally while simultaneously avoiding obstacles. The objective is to create predictable, repeatable, and explainable vehicle behaviors, demonstrating the autonomous vehicle's ability to generate effective solutions tailored to each specific scenario. By focusing on optimal, pattern-based near-field path planning, this thesis addresses the challenge of navigating complex intralogistics environments, ensuring maximum efficiency and safety in operations. This approach not only enhances the vehicle's performance but also showcases the potential of autonomous technology in transforming modern intralogistics.

This work encloses 4 chapters:

- **Chapter 1** gives a deep insight about the host company's structure, activities and products. Then it dives into the project context and its motivations, the work methodology, the studied problematic, and the fundamental aspects of the work.
- **Chapter 2** delves into the state of the art of the work area, then goes through a review of the literature that served as a base of the thesis and gave an overview of the existing solutions. Finally, it presents the methodology followed in the course of the thesis work.
- **Chapter 3** explains the development steps of the approach: it explains the geometric division of the stations into transition zones, details the path creation methodology, presents the mathematical aspect of splines and their implementation in robotic path planning, discusses the studied path discrimination approaches, and finally it explores the optimization approaches for the local path planning problem.
- **Chapter 4** explicits the tests of the developed approach in the RACK simulation system, then on the automated vehicle, using different test scenarios and states and analyzing the obtained results.

Chapter 1

Host company and Project context

Chapter 1

Host company and Project context

Introduction

This chapter is reserved to present STILL GmbH as the host company, its organizational structure, the mother company KION group. It will then proceed to describe the range of products that the company produces. The second part is dedicated to set the project context by explaining the problem statement, the motivation behind this thesis project, and its specifications. The final part will emphasize the work methodology adopted to carry out this project.

1 | Host company: STILL GmbH

This section introduces the host group and company through their activities, products, and activities

1.1 KION Group and STILL GmbH

STILL GmbH, based in Hamburg, Germany, is a leading manufacturer of intralogistics solutions with 14 locations in Germany and a global sales network spanning 246 locations. Operating under the KION Group, Europe's largest forklift truck manufacturer, STILL boasts over 100 years of experience. The company develops highly efficient, client-tailored products, serving businesses of all sizes with a wide range of forklift trucks—from manually driven forklifts to high-reach trucks and

fully automated vehicles—alongside consultancy services and software solutions.

STILL prioritizes smart logistics and energy optimization while maintaining award-winning product quality, catering to industries such as food and retail, automotive, and electronics. Employing over 9,000 people across departments like sales and marketing, research and development, production, mechatronics, and quality assurance, STILL remains at the forefront of intralogistics innovation.

KION Group is one of the global leaders in the fields of industrial trucks and supply chain solutions. It is the mother company of: Linde, Dematic Baoli, OM, Fenwick, and STILL who produce the goods and services of the group as detailed in Figure 1.1.

Present in 4 continents and hiring more than 42000 employees, KION's strategy is to ensure profitable and sustainable growth while focusing on Automation and robotics deployment as one of the main leaders of this growth.

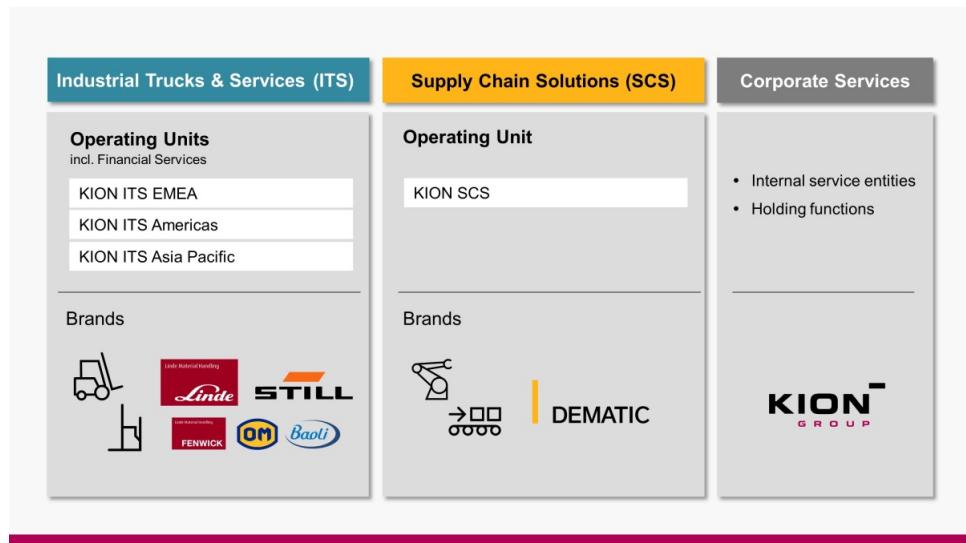

Figure 1.1: KION segment services and companies [1]

1.2 KION Management Hierarchy

The company is composed of departments managing the operations in all companies that are divided by scope of interest like R&D, Management, finances, etc.. Figure 1.2 illustrates the different areas of responsibility of the Executive Board. The Autonomous vehicles team belongs to the Mobile Automation department under CTO.

1.3 STILL Products

The 2017-established Autonomous vehicles team aims to develop fully automated solutions that leverage novel technologies to create innovative services delivered through forklift trucks. The vehicles are developed while keeping safety and high-performance as the main priorities.

iGo neo shown in Figure 1.6 is one of the main products developed by the department, it is a low level order picker transformed into the agent's autonomous assistant. Functioning in autonomous or semi-autonomous modes, it can follow the operator and their pace while avoiding obstacles and perceiving their surroundings as well as pick and place pallets in designed areas. Its added value is in preserving ergonomics of the operators by preventing heavy load carrying for long distances and decreasing the driving ascents and descents by 75% thus increasing the personal and collective performances [3].

Figure 1.2: KION Executive Board responsibilities as of 01.2024 [2]

As STILL specializes in forklift trucks, it counts many other products. Trucks are either Diesel or Gas fueled, or electric trucks that use Li-Ion batteries. Depending on the client's warehouse type, they can choose from a vast range of reach trucks Figure 1.3, hand pallet trucks Figure 1.4, double stacker trucks Figure 1.5, and Automated industrial Trucks Figure 1.6 [4]. A small selection of the vast range of STILL products is presented here. Automation can be applied to driver-requiring trucks to fully automate them.

Figure 1.3: STILL reach truck

Figure 1.4: STILL hand truck

Figure 1.5: STILL rider truck

Figure 1.6: STILL Autonomous order picker

Despite the impressive capabilities of the iGo neo and similar autonomous vehicles, the implementation of such advanced technology brings up several challenges, particularly in ensuring reliable and predictable behavior under all operating conditions. This leads to a key motivation for further investigation and improvement in the field. The next section focuses on the process followed during the development of the project.

2 | Work Structure and Methodology

Our team adopts an Agile Scrum methodology showcased in Figure 1.7 to ensure efficient and flexible project management. Here's how we approach our work:

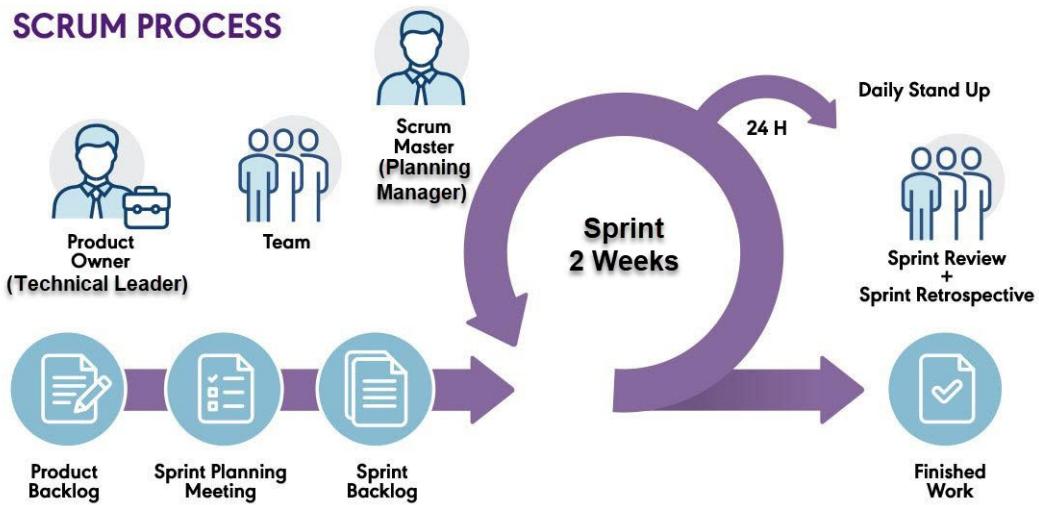

Figure 1.7: Agile Scrum Process [6]

2.1 Agile Scrum Framework

To follow the Agile Scrum framework 4 main tools/ are used:

- **Jira:** We use Jira to organize and track our tasks and progress. Jira allows us to create and manage tickets, which are detailed records of tasks, bugs, or features that need attention. Each ticket is assigned to team members and tracked through its development stages until completion.
- **Sprints:** Our work is organized into 2-week sprints. Each sprint is a focused period where we aim to complete a set of predefined tasks. At the start of each sprint, we hold a meeting to review the previous sprint: every team member presents their completed tickets, and communicates the changes or blockers that appeared during the process and plan for the next sprint: decide which tasks will be tackled during the sprint. This helps us maintain a steady pace and regularly deliver increments of our project.

- **PI Planning:** Every quarter, we engage in Program Increment (PI) planning with the mobile automation teams. The PI happens in two phases: each team prepares their planning for the next 3 months, then it is discussed and tailored again in a bigger round. This planning session helps us align our goals and strategies for the upcoming quarter. We review progress, set objectives, and coordinate with other teams to ensure that our work is aligned with broader project goals and company vision.
- **Daily Standups:** We hold 15 minutes long daily standup meetings to keep everyone on the same page. During these meetings, team members share updates on their progress, discuss any challenges they are facing, and outline their plans for the day. This practice promotes transparency, communication and quick problem-solving through collaboration.

2.2 Version Management

For Version Management, the team collaborates over **GitHub**: We use GitHub for version control and code management. GitHub allows us to collaborate on code, track changes, and manage different versions of our project. Each team member can contribute to the codebase, and we use pull requests to review and integrate new features.

2.3 Communication and Collaboration

For daily communication and effective organization, the following tools are put to use:

- **Microsoft Teams:** We use Microsoft Teams for real-time communication and collaboration. Teams provides a platform for chatting, video calls, and sharing files, facilitating smooth and efficient interactions among team members.
- **Microsoft Outlook:** Outlook is used for email communication and scheduling. It helps us manage meetings, track important messages, and coordinate tasks and deadlines.

2.4 Project Timeline

By integrating these tools and practices, we ensure a structured yet flexible workflow, enabling us to adapt to changes, communicate effectively, and deliver high-quality results.

3 | Graduation project Motivation and Problem Statement

3.1 Motivation

While autonomous vehicles can be highly reliable and efficient in carrying out various tasks, their behavior is not always predictable or easily explained. The output often exhibits a stochastic nature. For example, an obstacle-avoiding solution planned by the autonomous vehicle may be safe and correct but might follow an unusually shaped path.

Such stochastic behaviors can lead to a lack of trust and interest in robotized forklift trucks from a customer's perspective. This unpredictability can cause customers to question the system's repeatability, fearing that it may not perform consistently in critical situations. Moreover, the unexpected nature of these behaviors can make it difficult for operators to understand and anticipate the vehicle's actions, further reducing confidence.

Adding to these concerns, many autonomous systems, particularly in the intralogistics sector, require significant commissioning efforts before they can be implemented in a new environment and begin their service. Whether it's a required software integration, sensors installations, or measurements, these systems demand substantial time, information and financial investment—three crucial resources that STILL aims to optimize. Innovation in automation should involve the development of optimal solutions that are easy to commission in a new environment. These so-called "plug-and-play" solutions reduce the effort required and allow customers to start benefiting from the autonomous features with just the physical truck on-site and available information about the warehouse. the rest, is online recognition and processing. This approach significantly enhances the impact and convenience of the technology.

The autonomous vehicles department focuses on creating reliable, efficient, and explainable systems to build trust with customers, encouraging adoption of the technology. With a focus on explainable AI, the technology becomes more interpretable, helping customers understand decision-making processes and increasing their confidence in its safety and reliability.

3.2 Problem statement

Autonomous navigation is a topic where explainable intelligence can be integrated. Robotic forklifts execute missions such as transporting pallets from one place to another: picking up or dropping pallets. A typical mission is splitted into:

- a movement to a source
- a pickup
- a movement to the destination
- a drop

The movement to the source or the destination is exemplified by figure 1.8 where *station1* is considered the source station that the truck is headed to. However, the truck arrives at a distant pose from the shelf or pallet, the distance is clearly seen in figure 1.9. In addition, its forks are facing the wrong direction because driving the truck should happen like the arrow shows on figure 1.8 to avoid hitting humans or materials with the forks. The distance is intended because the truck needs a maneuver to make its forks dock (enter) the shelf as they are the part that picks up or drops the pallet. This work focuses on the subtask of an autonomous online linking of the vehicle to the shelf independantly from the task to be performed (pick up/drop).

The path that involves this maneuver is called the "link path" that guides the truck to the pallet or the drop pose which is the shelf inside the station as illustrates figure 1.9. Online linking of the robotic forklift to the goal pallet or location takes place inside the station. Online linking is mandatory because warehouse areas are subject to constant changes for instance, shelves can be shifted from their expected position and dynamic obstacles can show up, but, the vehicle needs precise recognition of the coordinates that it will reach. Precise recognition allows for correctness of the picking or dropping processes, otherwise, the task can fail. Furthermore, the vehicle has to account for the new obstacles and clutter inside of the station and avoid collisioning with them when driving to the destination shelf.

When it arrives at the station, the vehicle is fronted by these constraints:

- The vehicle's forks are not facing the destination shelf as shown in figure 1.9 but rather the opposite direction, so a driving direction change is needed.
- The vehicle is bulky in volume and mass (1200 to 4000 kg) with an overall length of 2500 to 4000 mm [5] which makes it challenging to change directions: turning on the spot or navigating in highly curved paths.

- The pallet docking process has to be very precise to avoid shifts and mistakes.

Figure 1.8 is a section of the model of a real warehouse. In this work, the interest is around the following items of the model:

- Dark Blue outline: walls of the warehouse
- Yellow Rectangles marked as stations: Warehouse stations: Actions like picking up or dropping are performed in specific locations inside the warehouse called stations, examples of which are named *station1*, *station2*, and *station3* on the figure 1.8. Each station is designed to support specific warehouse functions and their general mission is to facilitate and organize material handling operations. Each station contains a **shelf** that contains the pallets to be picked or dropped.
- Black rectangles: storage shelves (also called racks), where the pallets and material are stored.
- Turquoise blue lines: Global paths that connect the stations. The truck takes these routes when navigating from a station to the other while avoiding obstacles online if they occur.
- Gray rectangles are starting position of the truck around the warehouse. For instance, the truck can be placed at these positions before starting its autonomous navigation and task fulfillment.

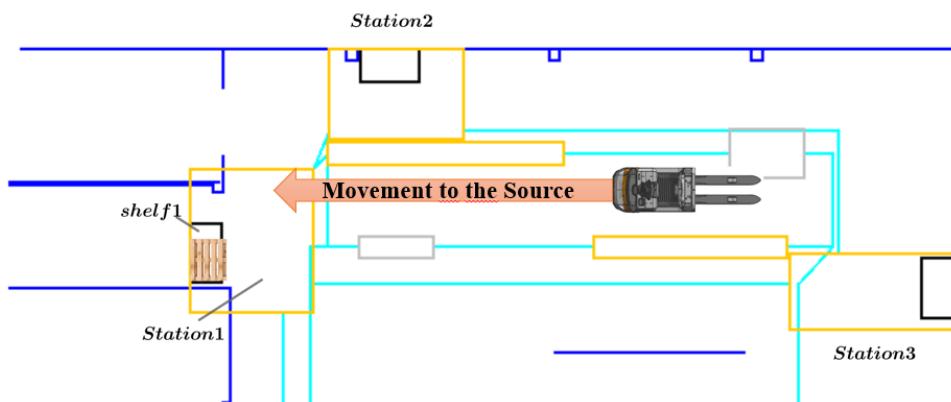

Figure 1.8: Vehicle Moving towards station 1

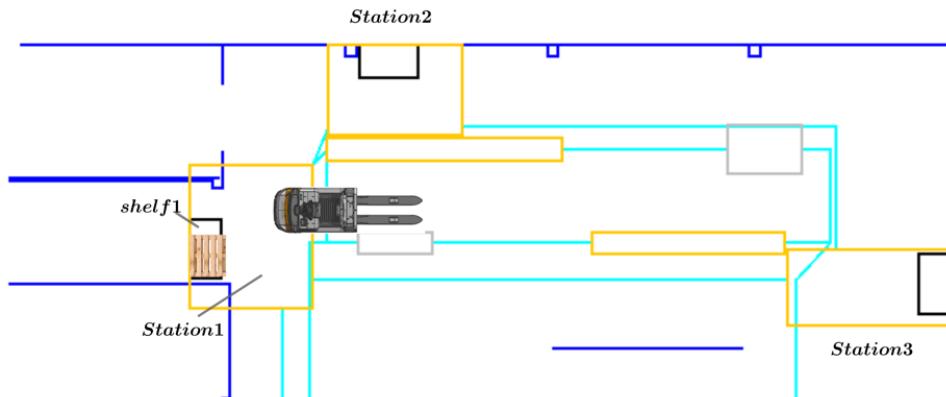

Figure 1.9: Vehicle arrives at station 1 and ready to execute the task

To summarize, the goal is to autonomously and optimally transport the vehicle from the position of entering the station in figure 1.10 to the position of docking the shelf in figure 1.11 while accounting for obstacles, kinematics of the vehicle, and maximizing speed.

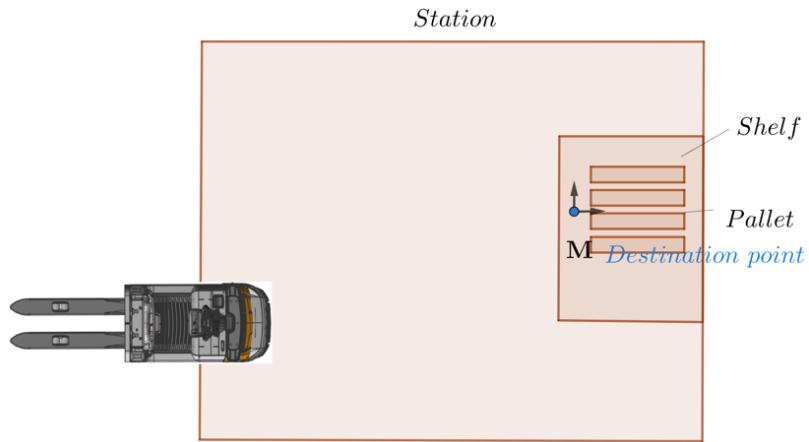

Figure 1.10: Vehicle entered the station waiting for docking the shelf

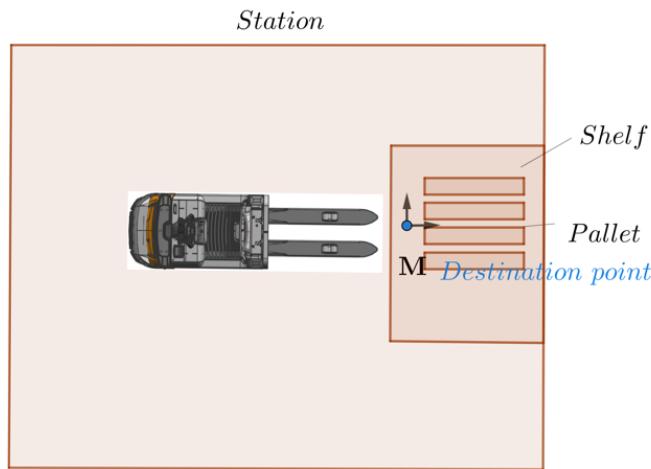

Figure 1.11: Vehicle docked the shelf

The next chapters lead to the available approaches, the goals to be fulfilled, and the methodology to address the problem statement.

Conclusion

This chapter introduced the host company, STILL GmbH, and its role within the KION Group, highlighting its management structure and product offerings. It also outlined the motivation behind the graduation project and the specific problem statement it aims to address. The chapter provided an overview of the work structure and methodology, focusing on the Agile Scrum framework and key tools for version management. Additionally, the importance of effective communication and

collaboration throughout the project was emphasized. These foundational elements set the stage for the detailed work in subsequent chapters.

Chapter 2

State of the Art: Optimal path planning for autonomous robots

Chapter 2

State of the Art: Optimal path planning for autonomous robots

Introduction

This chapter focuses on a synthesis of the literature around Optimal Near-field Path planning for robots in Intralogistics environments. It starts with an explanation of the fundamental aspects this work is based on as Automated Mobile Robots (AMRs), Near-field Path planning and Optimization techniques with a focus on Intralogistics. Then it focuses on the path planning approaches proposed to rise to the existing challenges. Later, the topic of optimization is outlined, investigating the decision-making science that leads to the elimination of some path planning drawbacks. It concludes with a discussion around which works from the literature can be used for this problem statement and how they can be exploited for this work.

1 | Intralogistics Environments

Intralogistics refers to the management, control, and optimization of internal material and information flow within a warehouse ???. It encompasses all physical and operational processes involved in the movement of materials and goods. This concept was introduced and defined by the German Engineering Association (VDMA). Figure 2.1 covers various aspects of intralogistics areas, including the storage, transportation, supply, Manufacturing, and disposal of production materials, as well as shipping. The scope of this work is focused around the warehouse area where storage: picking,

and placing, takes place. In brownfield applications, introduced in the General Introduction, the warehouse environment is usually a crowded and cluttered atmosphere: The nature of activities like manufacturing storing installs a high level of dynamics, whether it is operators or other vehicles, and obstacles as boxes and pallets. The cluttered and highly dynamic nature of this environment makes it challenging to successfully implement robotic based solutions.

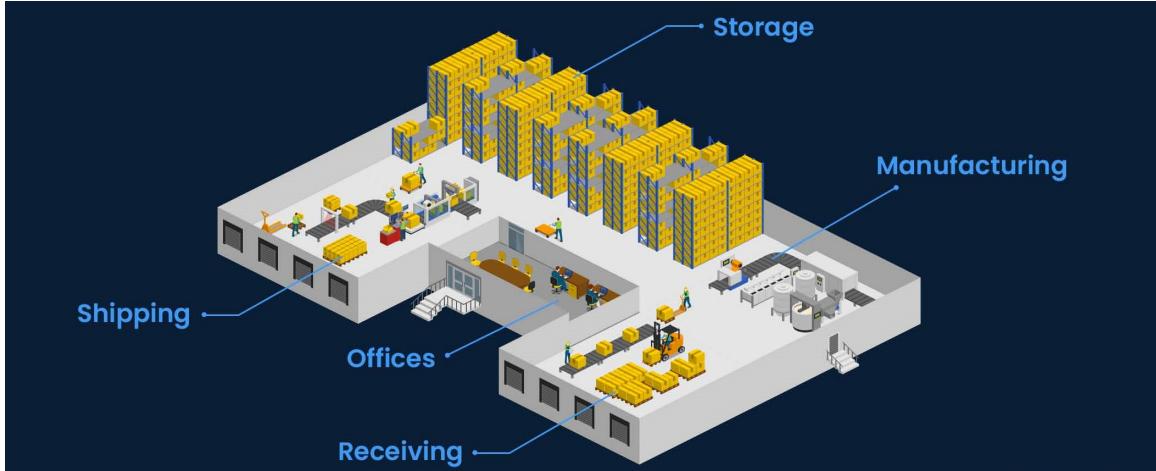

Figure 2.1: Common Intralogistics Environment Areas [46]

2 | AMRs in Intralogistics Environments

Autonomous Mobile Robots (AMRs) are advanced robots designed to navigate and perform tasks independently in dynamic environments without the need for fixed infrastructure or human intervention. Equipped with sensors, cameras, and advanced software, AMRs can move around facilities like warehouses and factories, adjusting their paths based on real-time conditions. They are commonly used for material handling and transporting goods [7].

AMRs are a type of non-holonomic vehicles. Non-holonomic vehicles are systems whose movement is subject to constraints that limit their ability to move freely in all directions. Specifically, their constraints depend on their configuration and velocities, meaning they cannot instantaneously move in certain directions (e.g., sideways), but must follow a specific path or series of movements to achieve certain positions. This contrasts with holonomic systems, which can move in any direction directly without such constraints [28].

In the Intralogistics field, AMRs were introduced as a revolution to Automated Guided Vehicles (AGVs) [7]. First introduced in 1955, AGVs performed tasks like material handling. AGVs are

managed by top-level software that handles task planning, providing the vehicles with intermediate waypoints to navigate from start to end points [7]. On the other hand, AMRs are automated in a way that makes them find the solution to unexpected problems, in fact: Figure 2.2, shows the difference in behavior between an AMR and an AGV in the case of a new obstacle. While AMRs are able to surpass the obstacle through sensors recognition and obstacle avoidance algorithms, AGVs require human intervention to eliminate the obstacle before restarting the navigation.

AMRs fit in the cluttered areas of warehouses. Their perception of the surrounding information allows for low commissioning efforts: they are able to localize themselves, plan then navigate to the goal and reach their destinations autonomously. Their operation does not require an expert or an engineer's intervention which limits the commissioning and utilization costs.

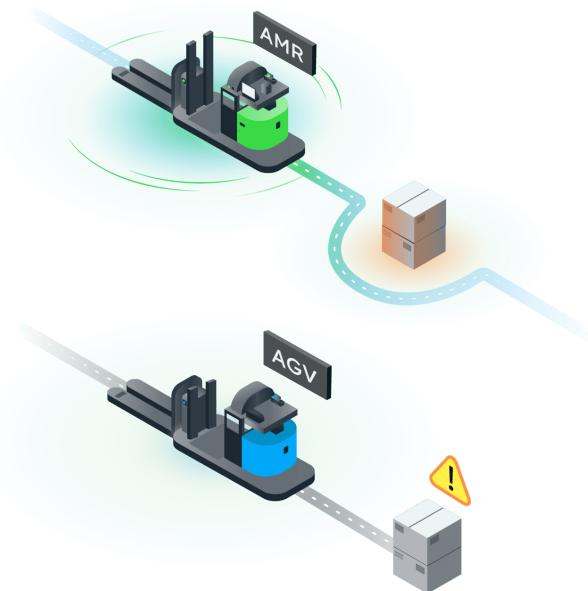

Figure 2.2: AMR and AGV behaviors at presence of an obstacle [9]

3 | Path Planning

This section will dive into the path planning state of the art: outlining its promising opportunities and current challenges, detailing the different approaches, and discussing their efficiency and compatibility with the problem statement.

3.1 Path Planning for autonomous robots: Opportunities and challenges

Path planning for mobile robots involves creating and generating efficient routes for the robot to travel from a starting position (A) to a target position (B), ensuring minimal time and travel distance while avoiding collisions with nearby objects [7]. Literature differentiates between two main types of path planning: global and local path planning [11]. Global planning involves finding an optimal path from the start to the target position based on sensor input within a known, static environment, whereas local planning focuses on real-time path planning and obstacle avoidance, typically used online while moving to avoid dynamic obstacles [11].

In complex environments, movement and task fulfillment must be done carefully and accurately given the volume of the vehicle and the value of the handled material. With appropriate input from various sensors, such as laser scanners, cameras, and LiDAR providing robots can perceive of their surrounding environment and plan the right path accordingly. This hardware innovation made navigation flexibility and autonomous recovery after failure possible[7]. The relevance of efficient path planning, mainly in the intralogistics sector, is derived from the constant need of optimizing material flow, productivity rates, and cost effectiveness. Path planning reduces travel time and distances when moving goods and thus , improving overall operational costs by allowing robots to take the most optimal routes when moving goods. By minimizing unnecessary detours and avoiding congested areas, robots can complete tasks more quickly, leading to faster material handling cycles. In those dynamic environments (see chapter 2, section 1), operators and employees are moving around, goods and pallets are being transported or stocked, and materials must be handled safely and carefully. Flexibility in routing and planning, enables the AMRs to always drive the optimal path based on the space settings. This flexibility offers several benefits, such as:

- Independence from Human intervention if an unexpected situation raises -AMRs do not require assistance, unlike AGVs [7].
- Reduced energy consumption thanks to optimal, smooth and short paths that adhere to the vehicles' kinematics, allocated task and travel time.
- Robustness and responsiveness thanks to decentralized decision making: enables fast recovery and change of strategy after failure[7].

Efficient path planning is critical for ensuring safe and reliable handling of objects in dynamic environments. By maintaining safe distances from both static and moving obstacles, including people, and continuously detecting surroundings, robots can ensure safety at all times. An optimized path improves both the length and smoothness of travel, minimizing travel time and boosting productivity,

as tasks are repeated frequently throughout the day. As a result, it enhances operational efficiency, contributing to overall system performance.

AMRs, as the name suggests, are standalone systems that must compile and process such input and generate, through algorithms, efficient paths. Path planning serves as the crucial link between the robot's sensor input and its motion control [10].

More than 60 years have elapsed since "Shaky" the first wheeled robot was running its first tests in Stanford University's labs. However, most of the robotic related topics are still being researched and improved. Dealing with all the aspects and challenges that robotics comes with can be very intricate. One of the major topics posing challenges to researchers is path planning. In [20], authors reviewed recent path planning approaches and challenges in dynamic unknown environments. Safety in path planning was the main concern for 29 % of the reviewed studies. Navigating efficient paths while avoiding collisions is challenging to accomplish. Collision avoidance is tightly related to perception input through sensors, analysis and use of the data. While it may seem simple for the robots to correctly analyze and recognize the objects around them, in reality, detailed understanding is not possible [21]. Issues are related to the accuracy of the sensors and the robustness of the algorithms. It is expected from the robot to perceive of the obstacles just like humans do, recognizing 3d shapes, dimensions, depth, direction and velocity, but from the robot's perspective, it is only able to recognize the outer surface that reflects the sensor's luminous signals. As shown in figure 2.3, the simulated robot (in gray) is surrounded by 3 obstacles (blue polygons). While the obstacles are polygon-shaped, the perception of the robot is limited to the surfaces that it can scan and does not see the hidden depth beyond these surfaces.

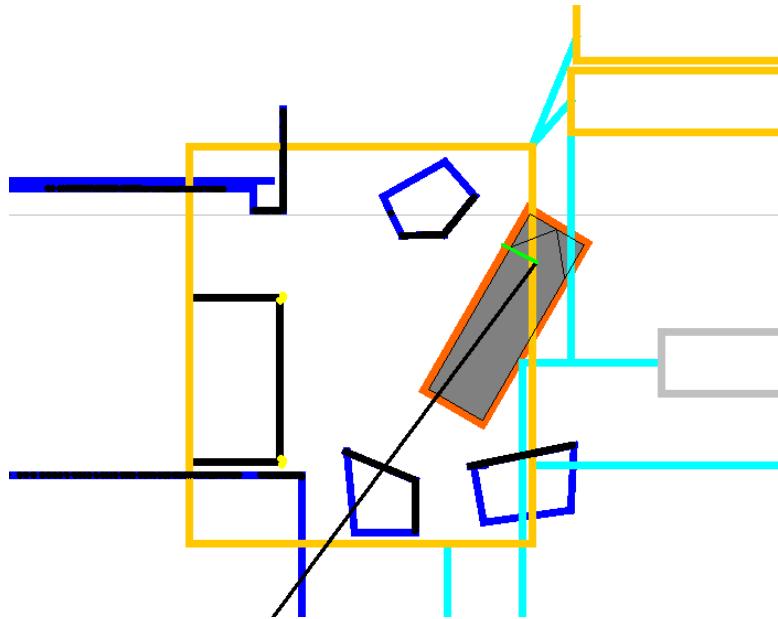

Figure 2.3: Simulation of the robot's perception of surrounding obstacles.

Yellow rectangle: Station limits

Black rectangle: Shelf limits: where to pick or to place pallets

In gray: Robot in simulation

Blue polygons: Simulated obstacles

Black lines: Perceived obstacle points

As a result, algorithms are to compensate the shadowed depth of obstacles by enforcing safety measures like keeping the vehicle at a safe distance from the obstacles and decelerating at the proximity of static and dynamic objects to avoid collisions ???. In addition, this input contains noises caused by the sensors reflections of other objects or inaccuracies ???. This makes it challenging to interpret the input and create deliberative systems as the built algorithms have to deal with the given data in all cases and detect the inaccuracies and noises. Beyond that, it is complex to generate feasible solutions in all types of environments, some planners and algorithms risk stagnating in a local minima and not converging to the optimal routes due to the limited knowledge of the environment and the sensory limitations previously mentioned ???. Figure 2.4 shows a simplified example of a potential wrong decision. A vehicle encounters two possible driving paths, similar to what might happen in a racking system. Based solely on sensor data (grey shaded area), the correct path cannot be determined. Only with global path planning (green path) can a long-term route be selected (black arrow), avoiding the risk of ending up in a dead end (red arrow). Assuming the global trajectory leads to the mission goal, any local deviations from this path should be kept minimal while avoiding obstacles.

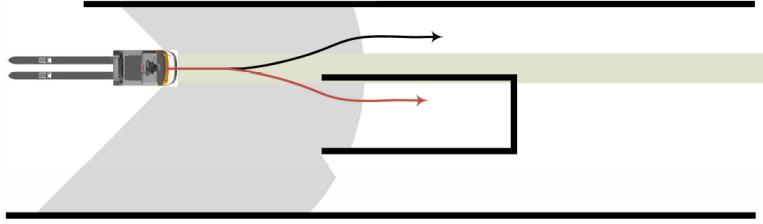

Figure 2.4: Model of a local minima problem due to limited sensor output [28]

Besides safety, computational cost is an interesting topic that researchers are looking at. In a real time context, it is important to synchronize different tasks, analyze massive amounts of data generated by sensors and camera like point clouds and 2d/3d images, and compute the required decisions in a reliable and accurate way. As the complexity of the environment increases, so does the computational burden, often leading to longer processing times or the need for more powerful hardware [23].

While managing computational costs is crucial, it is equally important to ensure that the paths generated are not only computationally efficient but also smooth and short, as these factors significantly influence the robot's overall performance. Given the kinematics of a robot, the destination's location and the clutter in the environment, path planners usually render rough paths. Cusps, which are sudden and sharp direction changes, and high curvatures of the path are unusual path properties that are hard to drive, energy and time inefficient, and require continuous decelerations and accelerations. Long paths are also not favored. While they can be necessary to avoid obstacles or to create a smooth path, longer distances result in time consumption and extensive energy usage. Some path planner include post-smoothing methods that modify the paths after its creation and intervene by shortening and smoothing paths areas while obstacles. In [23], Heiden et al. present approaches to implement post-smoothing methods like B-Splines, Shortcuts, Simplify Max, and vertex optimization. They conclude that different methods deal with certain improvements areas differently. For example, While Splines are outperformed in the curvature and cusps areas, they are efficient when it comes to path-smoothning computation time.

In conclusion, tackling robot path planning requires looking at several improvement areas: computational intensivity, smoothing, and safety at the same time. Most path planning approaches are effective in the aspects that they focus on, but lack optimization in others. This further emphasizes that these challenges remain under research and are not yet fully addressed in the literature. While these challenges highlight areas needing further exploration, path planning approaches propose techniques to address them. Understanding these approaches can provide insights into potential solutions and advancements in overcoming the existing limitations.

3.2 Near-Field Path Planning

Path planning can be differentiated into Global Path Planning (GPP) and Local Path Planning (LPP) or Near-Field Path Planning (NFPP). The GPP generates a global trajectory based on static and known environment model, such as the current pose, target location and the static components of the environment like shelves and walls [28]. The LPP generates relative trajectories and allows deviation from the previously generated global trajectory if disturbances in the travel path are detected. However, LPP tend to converge into local minima as explained in the previous section .

Due to the sheer number of publications around LPP, the work of Krüger-Basjmeleh [28] clusters processes into 4 groups. Figure 2.5 illustrates 4 clusters. The classification of the methods is done by dividing them into direction, speed, and path generating methods and other methods based on AI for NFPP. All methods rely equally on immediate sensory input from the environment as the basis for future tracking strategies.

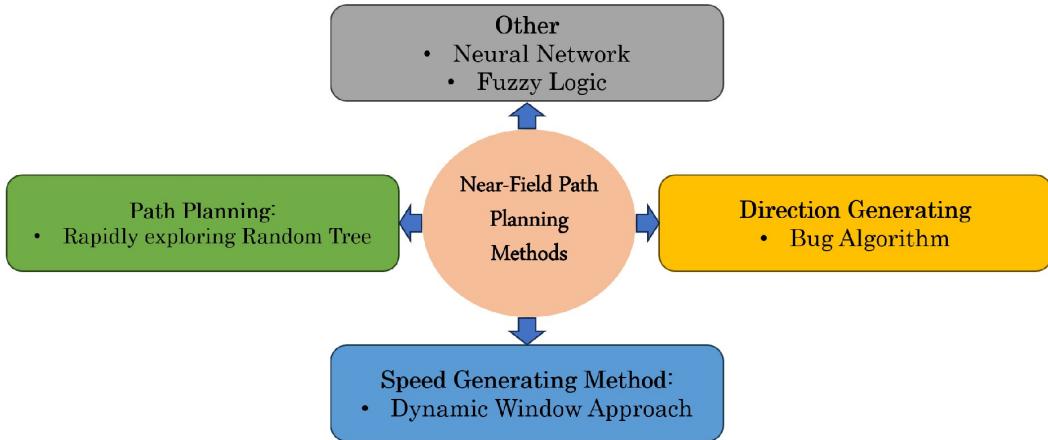

Figure 2.5: Clustering Of Near-Field Path Planning Approaches [28]

The process groups are then differentiated to identify their advantages, limitations and suitability to the problem statement. For each cluster one or two methods are studied and explained, through which the discrimination is made.

Direction-generating methods compute feasible travel directions (directional state space) based on sensory input, which the AMR should follow in the next time step [28]. A very simple algorithm for obstacle avoidance is the Bug algorithm. In their research paper [25], Buniyamin, N. et al. propose the point to point Bug algorithm to navigate in unkown environments. Bug algorithms

are based on range sensors input. As illustrated by 2.6, the robot at the starting point (Start green dot), plans to move directly to the Goal (Goal Red dot). Then it rotates scanning for obstacle points. If it encounters a sudden obstacle point (*A*), it navigates in its direction. The robot rotates in the target's direction (*B* then *C*) until it is able to resume its direct path to the target based on the constant search for the shortest distance from the current standpoint or find the next obstacle.

While this approach is simple from the computational point of view and the hardware used, it may not be optimal considering other metrics. First it can be significantly affected by sensory noises. Besides, its path length optimality depends on the nature of the environments and the number of obstacles and its efficiency decreases if the complexity (obstacle density) of the test area increases: in figure 2.6, the path rich in vertices : start-A, A-B, B-C, and C-goal, which makes it long and lacks optimization.

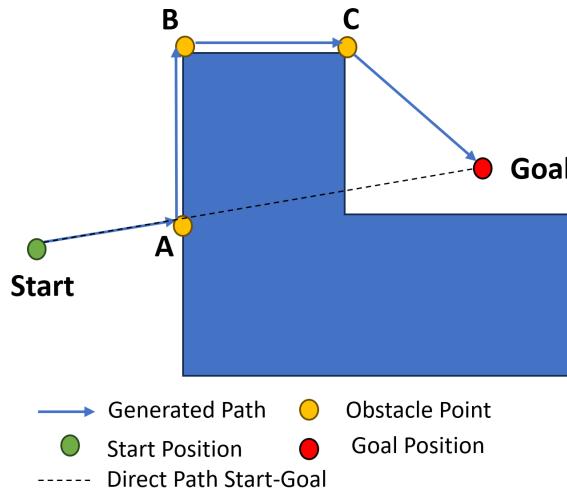

Figure 2.6: Bug Algorithm Path Solution to navigate from Start to Goal while avoiding the obstacle

Velocity-generating path planning methods are algorithms used in AMRs, to calculate both the speed and direction of movement. They predict the rotational and translational velocities creating the state space of velocities and taking into account the sensory inputs [28]. The Dynamic Window Approach (DWA) is a Velocity-generating path planning method.

In [19], Liu et al. used Djikstra ALgorithm (A path-generating Algorithm) for Global path planning and the DWA as the local path planner for sudden unkown obstacles that could appear for smart cars while following the global path. It works by evaluating different possible movements the robot could make within a short time frame and choosing the one that avoids obstacles while also moving towards the goal. The "window" refers to a limited set of possible velocities of the velocity space the robot can use based on its current speed and capabilities. Figure 2.7 details the flowchart

of the DWA.

The DWA algorithm starts by analyzing the car's position and base data. It then samples the speed and generates a range of possible trajectories. Each trajectory is evaluated to check if it will collide with obstacles. If a trajectory is collision-free, it's considered for optimal trajectory selection. This process continues until all possible trajectories have been evaluated or an optimal one is found. The combined algorithms were tested on 3 spaces with 3 stages of environment complexity ranging from simple to complex. However, the tests were effected with dynamic obstacles only inside the simulation and soit is subject for the reality gap problem. While these methods excel at avoiding obstacles at high speeds, they struggle with local minima. This is because they don't consider the overall structure of the free space when evaluating movements. Additionally, these velocity-generating methods have limitations in mapping the future movements of non-holonomic platforms. For example, a method might suggest a movement that is impossible for the vehicle to perform due to its non-holonomic nature [28].

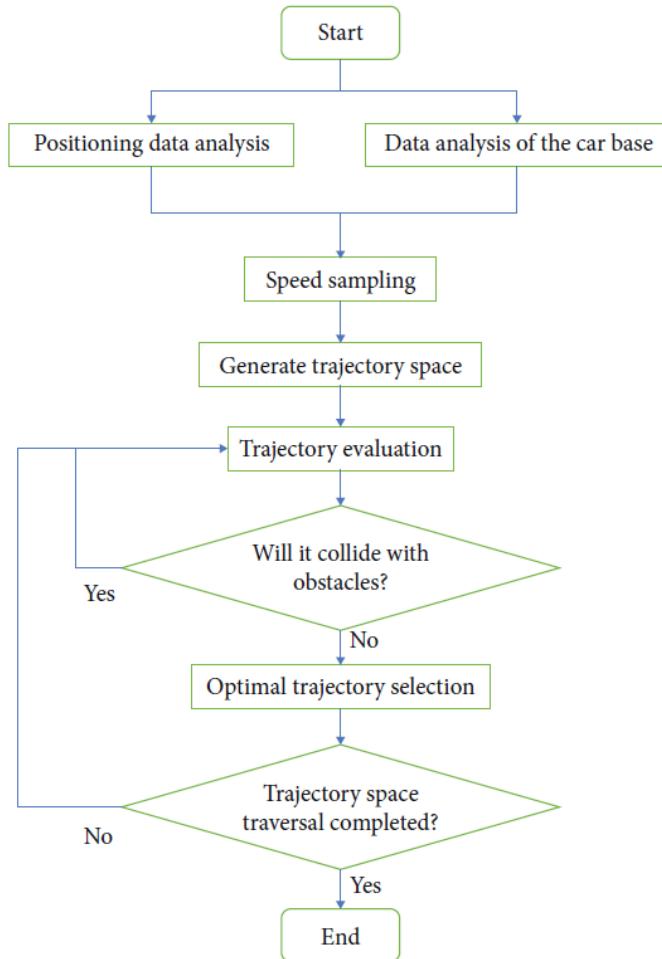

Figure 2.7: Flowchart of the DWA [19]

Path-generating path planning methods plan entire trajectories in advance, considering both the vehicle's position and its intended path over time. These planned trajectories are then combined with the previously calculated overall path. Currently, various path planning methods are used in both industry and research [28]. For example, A* Algorithm is a Path-generating Grid-based method where the environment is partitioned into a grid of discrete cells, where each cell represents a portion of the space. The algorithm then traverses these cells to identify suitable paths based on factors such as occupancy or cost. For example, in the A* algorithm, the fitness function is calculated from the start point to the reached cell, while in the Dijkstra algorithm, it's from the reached cell to the destination. While this approach offers a straightforward understanding and implementation, its computational cost can be significant due to the large number of cells to evaluate and the repetitive nature of the calculations. Additionally, grid-based methods are often constrained by the fixed directionality of the grid. The paths generated are restricted to the directions defined by the grid. For instance, if the grid is aligned along the x and y axes, the robot can only move horizontally or vertically. This can be inefficient or even impossible in environments where diagonal or more complex movements are required. On the Other hand,

Lavalle [47] created a method called Rapidly-exploring Random Trees (RRT), a randomized data structure used for various path planning tasks. It starts with a single node (usually the starting point) and iteratively grows a tree by adding new nodes. At each iteration, a random point is sampled from the search space. The nearest node in the tree is found, and a new node is added along the path to this random point. This process is repeated until a path is found or a maximum number of iterations is reached. RRT is particularly effective for exploring complex environments with obstacles. Figure 2.8, illustrates the test of RRT in an obstacle-rich environment (shown in blue) using 1, 4, then 32-core processors. The planned paths (branches) are shown in grey. The path calculated as optimal is shown in red and connects the start pose with the goal pose. These algorithms present advantages like handling big environments and complex obstacle situations, however, they can also be computationally intensive and demanding in complicated situations. Figure 2.8 shows the difference in the resulting optimal path in a cluttered environment where with 1 core the algorithm successfully finds a feasible path, and, as the cores double, the computed path improves its quality as the search tree expands. RRTs require collision checks for each new node, which can be computationally expensive and memory-intensive, especially in environments with numerous obstacles, heavy traffic, or complex paths.

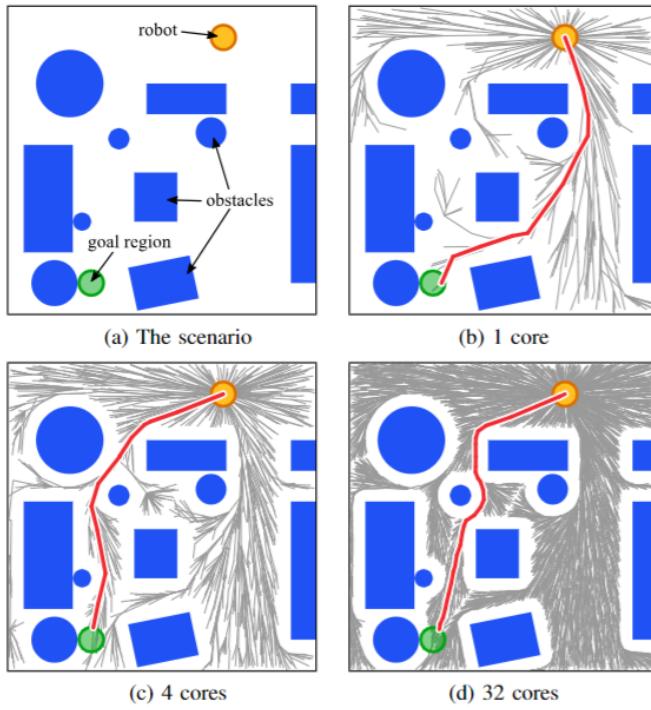

Figure 2.8: RRT ran on a non-holonomic robot using 1, 4, then 32-core processors [16]

Artificial Intelligence-based methods leverage the use of Neural Networks, Fuzzy Logic, Reinforcement Learning, and Evolutionary algorithms. These methods learn from experience, adapt to changes, and optimize paths in complex environments.

To start with, Neural Networks (NN) are inspired from the biological harmonious connection of the brain neurons that gives it the ability to process big amounts of data and generate ideas and decisions and solve problems. The NN is built in a way that enables it to get its input in a form of data and process it by learning, improving and adjusting the output to the desired results. NN are able to perform Parallel processing: the information is transmitted in two directions to the neuron in the case of Recurrent Neural Networks (RNN) that allows for learning from current and past inputs to the NN. This approach improves the computation time and overall performance. The NN is then able to process solutions that create paths for difficult environments. However, it presents a practicality challenge. Although the performance and results can be impressive, yet, in a real-time context, it is unfeasible to rely on solutions that require extensive computational efforts and need long durations to process solutions. In addition, the number of neurons and layers have to be scalable and depends closely on the level of complexity that the vehicle is to deal with: NN are trained using a usecase so the outcome is tightly related to that use case and is not as efficient in other applications [12].

On the other hand, Reinforcement Learning (RL) can be used to learn optimal paths by interacting

with the environment. The robot learns a policy that maximizes cumulative rewards, where rewards are given for reaching the goal, avoiding obstacles, and minimizing path length. The policy is often represented by a neural network, and the path is optimized as the robot learns from its experiences. Reinforcement learning (RL) methods for path planning in wheeled mobile robots face significant limitations due to high computational costs and long training times. These methods require extensive data to cover various scenarios, making the process time-consuming and resource-intensive. Training an RL agent, particularly in complex environments, can take millions of interactions, which is impractical for real-time applications. Additionally, as the environment's complexity increases, the state and action spaces expand, leading to scalability issues and longer training times. When combined with deep learning, RL becomes even more computationally demanding, requiring substantial resources and careful tuning of hyperparameters.

Fuzzy Logic (FL), on the other hand, is a way of thinking that mimics how humans make decisions, especially when things are unclear or uncertain. Instead of working with exact numbers, it uses "fuzzy" terms like "good", "average" or "bad" to make decisions. Input numbers are clustered following the fuzzy sets or intervals and assigned a value using membership functions. Later the values are interfered and defuzzified to genearte the ouput as a command value. In robotics and path planning, FL helps robots navigate by allowing them to handle uncertain situations, like avoiding obstacles or finding the best route, even when the environment is not fully known. Instead of needing exact data, the robot can employ fuzzy terms like "close" or "far" to understand its surroundings. For example, if an obstacle is "somewhat close," the robot can smoothly adjust its path to avoid it. FL also helps the robot choose the best route by weighing factors like distance, even when the information is not fine-tuned. This improves the robot's handling of dynamic environments and making flexible and optimal decisions. However, one disadvantage is that it can be tricky to create the right rules for the robot to follow, and the system can become complicated as more rules are added. It may present a scalability problem because in unpredictable and dynamic environments it is not evident to overfit fixed fuzzy sets to be practical in all of the cases [12].

While Neural Networks and Fuzzy Logic offer powerful approaches for handling uncertainty and complex decision-making, another key area in artificial intelligence for path planning is the use of meta-heuristic algorithms. Meta-Heuristoc algorithms are inspired from biological and natural processes for evolution and survival. Relying on environmental input like obstacles and targets, meta-heuristic algorithms explore the solution space by evolving random solutions for the problem and optimizing them by rounds until a stopping criterion or set of criteria is satisfied (see more in section 4: Heuristic Approaches). Approaches like Genetic Algorithms (GA) have been used for path planning by Ahmed Elshamli et al. [17]. The The robusteness of their solution is its adaption to dynamic environments. They evolve their GA using variable size chromosomes, where each node represents a waypoint of the path, then they measure the quality of each path using an evaluation

function. A modified Genetic Approach is then applied to each population: Crossover, mutation, **Repair** infeasible paths, **Shorten**, then **Smoothen** feasible paths while dynamically checking for new obstacles. The approach is tested in static and dynamic environments and has achieved proven efficiency when it comes to local optima challenges and surviving the best elements of the population. While the use of the GA itself is robust and successful, it can be challenging to recreate the algorithm and to add the improvements. In addition, the tests the ran are limited to a simple simulation with unrealistic situations and obstacle setting as displayed in figure 2.12: In reality, the hardware used to detect surrounding objects are scan based sensors for instance LiDAR. They scan 360° of the surrounding starting from the robot as the origin. This scan provides a polar perception of the obstacles (see figure 2.3). A polar perception only renders the perceivable surface of the objects. The objects' depth and dimensions are not available through this sensorial input. Obstacle perception is challenging due to limited knowledge of their exact contours and the discrete nature of optical sensor scanning. Connecting perceived points to form closed contours can be ambiguous, especially at a distance.

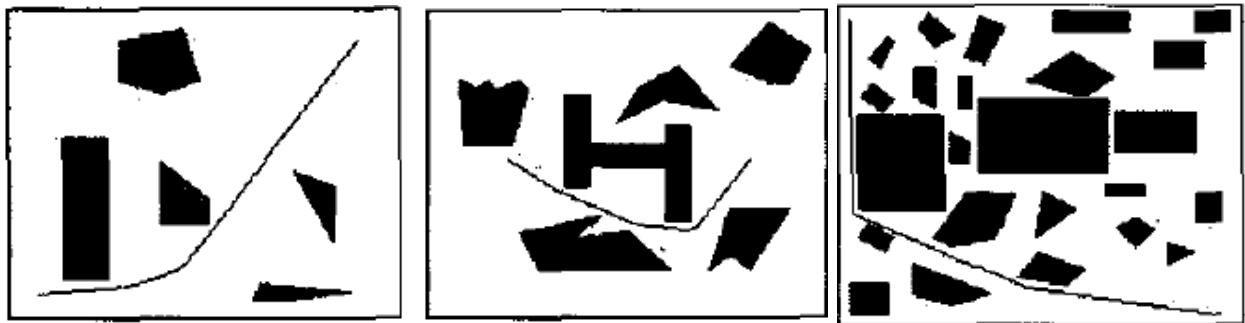

Figure 2.9: Simple obstacle environment

Figure 2.10: Intermediate obstacle environment

Figure 2.11: Complex obstacle environment

Figure 2.12: GA Test scenarios [17]

While Classic path planning methods (Path-generating, Velocity-generating, and Direction-Generating) have proven effective across various applications and usecases, they often face challenges when applied to highly structured, repetitive environments like those found in industrial automation. To overcome these limitations, the research in the previous years became rather oriented to investigating and using heuristic approaches. In [26], Masehian et al. conducted a chronological review about the followe approaches in Motion Planning (MP). The results testify that in 30 years, The application of Heuristic approaches in MP went from 0% to 54% from 1977 to 2007 as shown on Figure 2.13.

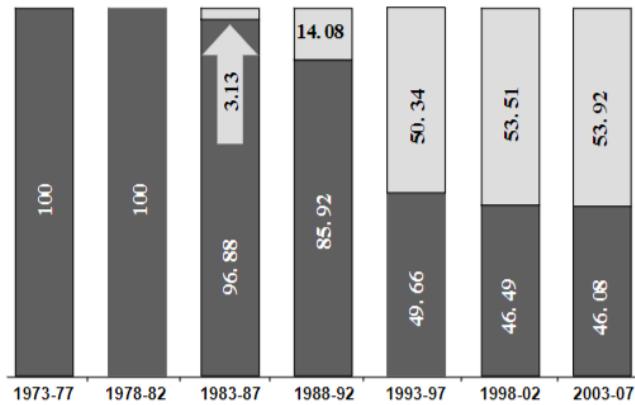

Figure 2.13: Application of classic and heuristic approaches in MP [26]

Dark gray: Classic approaches

Light gray: Heuristic approaches

To draw to a close, even though the heuristic approach prevails the classic one: [20] and [25], these approaches are not without their limitations. Heuristic methods, while good at navigating complex environments and avoiding local minima, sometimes fall short in finding the best possible solutions, especially in high-dimensional spaces.

3.3 Discussion: Selection of the Path Planning Method

Path-generating methods are particularly promising for intralogistics applications involving autonomous mobile robots (AMRs). Unlike direction-generating methods, these methods are well-suited for dynamic environments. These methods effectively handle dynamic environments and disturbances while minimizing oscillations and computational costs. They can also incorporate kinematic constraints and generate optimal trajectories in complex, unstructured areas. Compared to speed-generating methods, path-generating methods allow for dynamic planning horizons, enabling the calculation of optimal routes that avoid dynamic obstacles and disturbances. Given these advantages, this work will focus on path-generating methods for subsequent developments.

To enhance the efficiency and effectiveness of path planning, innovative approaches are emerging. By combining traditional methods with cutting-edge optimization techniques, we can overcome the computational challenges and achieve more robust solutions. These hybrid strategies offer a promising path forward, paving the way for advancements in path planning technology.

4 | Heuristic Approaches

This section will focus on the Application of heuristic algorithms for solving robotic path planning problematics.

4.1 Optimization Techniques

Optimization refers to the decision making led by the machine with availability of certain circumstances and constraints that either help or limit the outcomes of the optimizer [37]. In the case of path planning, optimization aims to modify some properties of the generated solutions to cope with the surrounding conditions. In stochastic environments, it is challenging to plan feasible paths given the high dynamics and obstacles. The increase in the complexity of the environment and the constant dynamics increase the number of variables involved in the mathematical representation of the problem. As a consequence, it raises the computation efforts that need to be deployed for the creation and optimization of the solution and decreases feasibility [7]. In order to get optimal results like smooth and short paths, finding a feasible path is not enough. The evaluation of the generated path and the optimization are helpful to ensure that the robot is driving the optimal path. There exists a range of planners and optimizers which are clustered as classic and Heuristic approaches [12]. Classic approaches include **Analytical** and **Enumerative** methods. The former rely on mathematical modeling, which can become unsolvable as the navigation environment becomes more cluttered. Additionally, applying these models can be challenging in scenarios where the necessary models for different components are not readily available. The latter have the drawback of increased intricacy in bigger or more elaborate search spaces. On the other hand, Heuristic approaches can be sub-categorized into **Meta-Heuristic** and **Evolutionary algorithms**. Some of these methods can fall in the trap of local minima and sub-optimality [12]. Alternatively, subsequent to a review of the available planning and control approaches in intralogistics, Fragapane, G. et al. [7], concluded that nature-inspired algorithms can instill intelligence into planned paths. Elshamli, A. et al. explained in [17], that Meta-Heuristics are adaptive to the dynamics of the surroundings unlike classic approaches that proceed sequentially to generate solutions. The paths developed by classic approaches can thus become infeasible in a later stage if the environment changes. Metaheuristic approaches are based on parallel search mechanisms that can have updated input of the conditions and thus are more adaptive and practical in real-world scenarios.

Next, this section dive into Meta-Heuristics which are defined by Bilal et al. as 'the optimization techniques mainly based on function evaluation and make little or no use of the properties of objective functions and constraints. Meta-heuristics are thus problem independent techniques not taking

advantage of any specificity of the problem' in their review [37]. The authors later break down Meta-Heuristics into **Neighborhood-based Algorithms** and **Population-based Algorithms** as given by the tree graph in Figure 2.14

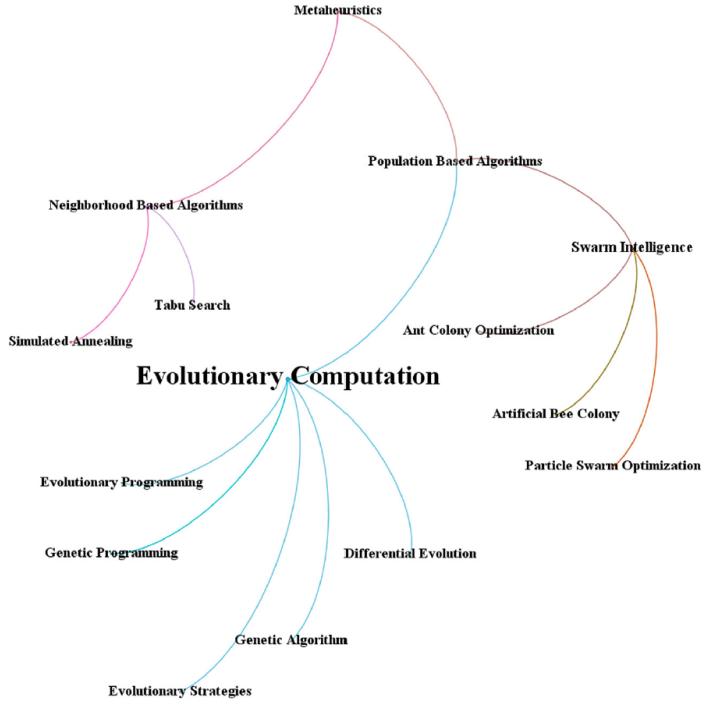

Figure 2.14: Tree of Meta-Heuristic Algorithms [37]

The Neighborhood-based algorithms benefit from the neighboring solutions by migrating from the current solution to the near surrounding solutions with the goal of improving the fitness function. The examples mentioned for this approach are Simulated Annealing (1979) and Tabu Search (1989). The Population-based algorithms are methods that start from a sample population and rely on their evolutions. They are inspired by the evolutionary processes observed in nature and are sub-categorized in this approach under Swarm intelligence and Evolutionary Algorithms. Swarm Intelligence approaches are analogous to the socio-cooperative practices of species like bees, ants, and birds. For instance, Ant Colony Optimization (1992) and Particle Swarm Optimization (1995) are examples of such algorithms. On the other hand, Evolutionary algorithms rather copy the species evolution theory, among which are Differential Evolution (1995) and Genetic Algorithm (1957) [37].

Metaheuristics, mainly Swarm-based methods and Genetic Algorithms, have been used multiple times for robotic path planning, as noted in the literature. Each algorithm has its own unique search methods and strengths, providing different benefits and areas for optimization.

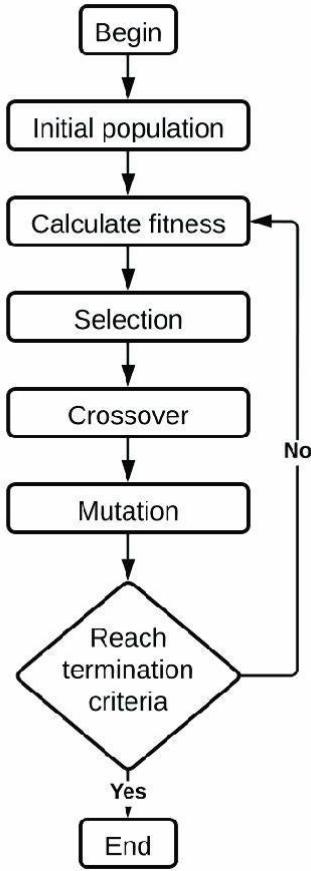

Figure 2.15: Flowchart of the GA [39]

Elshamli, A. et al. [17] have employed the Genetic Algorithm (GA) (See algorithm steps in figure 2.15) to solve the problem of path planning in dynamic environments. They represent their paths using chromosomes where each node of the chromosome represents a waypoint and develop a variable chromosome length approach that accommodates obstacle avoidance and efficiency in reaching the goal. The fitness of each chromosome is evaluated according to an objective function that includes path length, smoothness, and clearance to obstacles. A modified genetic Algorithm is applied where after crossover and mutation, paths are shortened and smoothed if it is possible. Saving the best individuals generated by the GA was effective in delivering the overall best solutions. Tamilselvi, D. et al. also modified the GA by applying the elitism concept.

This is achieved by saving the best individual, denoted as S_{best} , and replacing the worst individual in the next generation with S_{best} . This approach helps to prevent premature convergence to local optima, increasing the likelihood of finding the global optimum. In the context of path planning, elitism has proven effective in discovering feasible paths in environments with limited dynamic obstacles. Additionally, by incorporating a motion prediction mechanism based on the grid map, elitism

can be adapted to handle dynamic obstacles more effectively [38].

Authors of [40] also worked on the path planning in dynamic environments problem. They critic the GA to be computationally intensive and to require long planning time. Instead they suggest the Simulated Annealing algorithm (SA) to solve the path finding problem.

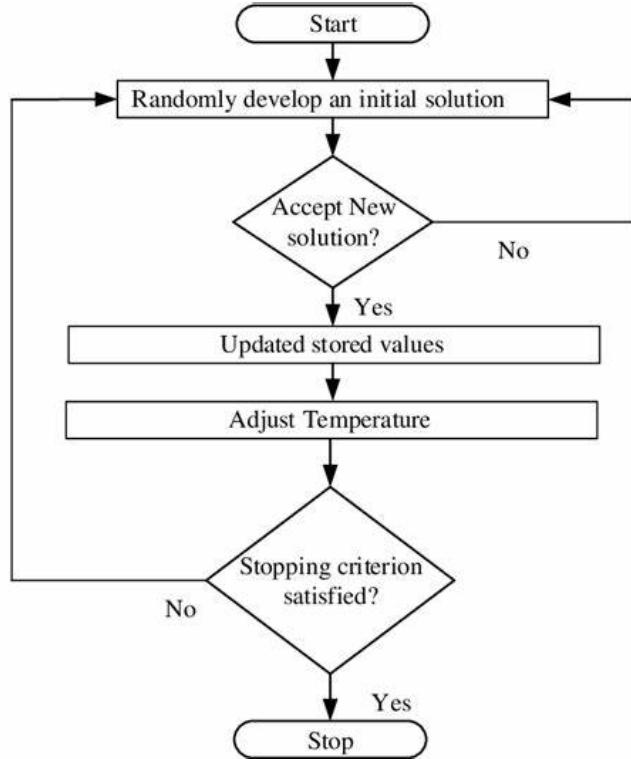

Figure 2.16: Flowchart of the SA [41]

Being a probabilistic meta-heuristic algorithm it is designed to guide the local optimum to a global optimum. The approach is based on the evaluation of the path length to discriminate path candidates: the shorter the path the better. It works by trying out different paths for the robot, beginning with a high "temperature" that lets the algorithm accept good paths and bad paths with a certain probability, which decreases over time (simulating the cooling process in annealing). This helps it explore a wide range of options and avoid getting stuck in a local minima. As the process continues, the temperature slowly decreases, making the algorithm less likely to accept bad paths, and helping it to focus on finding the global minima as given by figure 2.16. The algorithm was tested in four environments with different static and moving obstacles. The algorithm successfully found the best or nearly best paths and could quickly adjust to avoid collisions in real-time. Compared to a genetic algorithm, the SA method was 57% faster for complex environments and 74% faster for simple environments. However, the processing time increases exponentially for complex environments (13.57 seconds).

Particle Swarm Optimization Algorithm (PSO), as well, is used for solving non-linear optimization problems like scheduling, power management and also robotic path planning. It is inspired from the cohesive behavior of bird and fish swarms traveling together. It works by having a group of particles (potential solutions) move around in the search space to find the best solution. Each particle in the PSO algorithm remembers the coordinates of the best solution it has found so far, known as its personal best (pbest). Additionally, the algorithm tracks the best solution found by any particle, referred to as the global best (gbest). The core idea of PSO is to guide each particle towards both its pbest and the gbest positions: from state a to c as given by figure 2.17, using a randomly weighted acceleration during each iteration. The algorithm iteratively updates the particles' positions and velocities until an optimal or near-optimal solution is found. Alaliyat, S. et al. have investigated dynamic environment navigation using PSO. They found out that the performance of the algorithm depends on parameters tuning. Overall, feasible paths were successfully generated. Planning time is rather high for simply organized environments (18.35s) and higher for the most complicated scenario (31.17s).

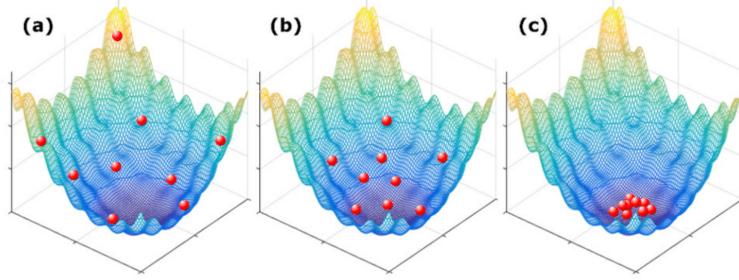

Figure 2.17: Particle Swarm Optimization [42]

Differential Evolution (DE) has been used in a hybrid algorithm along with PSO by Tand, B. et al. [43] to leverage both of the algorithms benefits. DE is rarely solely applied to path planning problems. In their review [37], of 20 years of research about DE, Bilal et al. did not mention robotics among the fields of application of DE. DE starts with a set of potential solutions. Each solution, or individual, is modified through mutation, crossover, and selection to improve over time. Mutation introduces random changes to create new candidates and avoid getting stuck in local optima. Crossover mixes parts of the new candidates with the original solutions to explore new possibilities. The selection process keeps only the better solutions for the next generation. This method effectively balances exploring new options and refining existing ones, making DE well-suited for complex optimization tasks. By integrating improved PSO and DE algorithms for enhancing particle diversity, Tand, B. et al. achieved better path quality compared to other methods. The results demonstrate that their approach outperforms traditional evolutionary algorithms in path optimality and optimize computation times by 1.38% [43].

Ant Colony Optimization (ACO) is known for being robust and good at parallel processing, but it can be slow and sometimes gets stuck in local optima solutions. To fix this, improvements like Ant Colony System (ACS) and Max-Min Ant System (MMAS) have been developed, which make ACO better at finding solutions but still have issues like being too rigid and converging too early. In mobile robot path planning, new strategies have been created to address these problems, such as adaptive methods that improve how pheromones are updated and balance exploration with finding the best path. Recent research has also introduced advanced versions like polymorphic ACO and multi-objective optimization, making ACO more effective for real-time and complex situations. However, these improvements also make the algorithm more complex and take more time to compute.

Meta-heuristic algorithms, such as Genetic Algorithms (GA), Particle Swarm Optimization (PSO), and Differential Evolution (DE), have become increasingly popular in robotic path planning. These algorithms are attractive because they can find good solutions to complex problems by mimicking natural processes like evolution or swarming behavior. However, despite their growing use in research and their potential efficiency in practical usecases, the application of meta-heuristic algorithms in real-world robotic path planning like the intralogistics field remains quite limited. One of the major issues is that most studies focus on simulations rather than testing in real environments. While simulations can help develop and adjust these algorithms, they do not fully cover the challenges robots face in the real world, such as varying conditions, surface types, or unexpected noises. Another major issue is how obstacles are represented in these studies. Often, obstacles are either unrealistically large compared to the robot or have overly simple shapes that don't accurately reflect real-world conditions. This lack of realism can result in algorithms that work well in simulations but fail when used in real environments. Additionally, because these algorithms are mostly tested in controlled, simulated settings, they may be too finely tuned to those specific conditions. This can make them less reliable when applied to the unpredictable conditions of the real world gap. In summary, while meta-heuristic algorithms show promise for robotic path planning, more real-world testing and realistic obstacle modeling are needed to ensure they work effectively in practical situations. Addressing these issues is key to advancing the use of robotics in intralogistics and other fields.

5 | Discussion

To synthesize the research conducted, it is paramount to summarize the **key concepts** comprehensively and point out the general **drawbacks**. This State of the Art report focuses on mobile robot path planning, a critical component of the overall robotic planning process. Effective path planning not only organizes and optimizes a robot's navigation but also significantly enhances its productivity by enabling it to execute missions more efficiently. In dynamic environments, a well-designed path planner is essential for ensuring safe operations and maximizing the robot's resource utilization and operational capacities. Meta-heuristic optimization algorithms are highly effective for refining mobile robot paths, particularly when building routes from scratch while considering both static and dynamic obstacles. They also have the capability to solve problems without information about their mathematical model. This has the great advantage of reducing the burden of expliciting the situation in order to solve it especially in complex cases where the effort to model the problem and the constraints is higher and, later, the computation is harder. Instead, meta-heuristic algorithms focus on optimizing the fitness function related to the specific usecase.

The path planning methods discussed have several drawbacks. Grid-based methods can be easily misled by noisy sensor data, and their generated paths might not be the shortest possible, particularly in crowded areas. Some methods excel at high speeds but struggle with dynamic environments, while others may have limitations in planning for non-holonomic vehicles. Computational efficiency is a concern, as some methods are slow and resource-intensive, especially in complex environments. Heuristic methods, while effective, might not always find the optimal solution. Real-world applications pose additional challenges. In dynamic warehouse settings, blocking areas for extended path planning can disrupt operations, interfere with other vehicles, and reduce productivity. Metaheuristic optimization approaches have been limited to mission scheduling in intralogistics robotics, with fewer applications in path planning. Addressing these limitations requires innovative solutions that balance computational efficiency, real-time performance, and path quality.

Furthermore, the classical and the heuristic approaches are capable of creating new different paths every time the algorithms are ran even in the same environment setting. While this phenomenon proves of the intelligence of the algorithms and the availability of several optimal paths, it makes the fully automated robot's behavior non-repeatable and unexplainable. For humans, it is difficult to foresee the behavior if many options are available. However, it is important for those working closely to robots to have an expectation of their behavior. It enables them to avoid collision risks and injuries and to plan their actions accordingly. If a predictable vehicle behavior is available, it promises a structured approach to path generation, reducing computational complexity and improving path quality.

Combining an optimal path planning approach that accommodates the kinematic constraints of Autonomous forklifts in the intralogistics environment and generates smooth paths, is behaviorally explainable and deploys meta-heuristic Algorithms is a new approach that would have an added value to mobile robot path planning in Intralogistics of reducing computation time and travel distance and improving AI driven solutions explainability.

6 | Adopted Path Planning and Optimization Methods

The above discussed Path Planning approaches are typically designed to solve path planning problems in various environments and have been used in multiple applications. For this project's problem, the robot operates in a consistent environment—the station. Although stations may differ in position, size, and layout, the components within them remain the same: shelves containing pallets. This consistency suggests that we should develop a solution specifically tailored to the station environment, which would help minimize potential problems and reduce the effort required to solve them.

A path planning module has already been developed at STILL for the autonomous forklift trucks, utilizing classic sampling-based path planning methods. This module is based on the Open Motion Planning Library (OMPL), an open-source library for motion planning in robotics. OMPL is designed for complex use cases and includes several algorithms, such as probabilistic roadmaps (PRM) and rapidly-exploring random trees (RRT), along with their variants. OMPL performs well in clean environments without obstacles, with a minimum processing time of $200ms$, but in complex environments, processing time can increase to $2s$. While it can be very fast in the absence of obstacles this approach presents some limitations:

- Not Station-Specific: While OMPL is a versatile and powerful motion planning library, its general-purpose nature can be a limitation for station-specific pickup/drop operations. OMPL is designed to handle a wide range of environments and tasks, but it may not be as efficient or tailored to the specific constraints and requirements of station-related operations. OMPL may not have built-in knowledge or optimizations for tasks like docking at specific stations, handling different station configurations, or considering constraints related to station-specific equipment.
- Too Complex for Simple Tasks: OMPL's advanced algorithms, while powerful, can be overkill

for simple tasks like pallet handling. Its general-purpose nature can also lead to computational overhead, especially in less complex environments. This suggests that tailoring OMPL to specific station-related operations could improve its efficiency and effectiveness.

- Long Processing Time: OMPL’s processing times can be substantial, particularly in complex environments with numerous obstacles, tight spaces, or frequent changes in the environment. This can lead to delays in decision-making and potentially hinder the overall efficiency of operations.

Given OMPL’s limitations, I propose a station-based approach is needed. This approach will be tailored to the structured environment of the station, enabling faster and more efficient path planning. By minimizing directional changes and adhering to station boundaries, we can achieve shorter and repeatable path calculation times, optimizing the overall efficiency of operations. By focusing on the typical tasks of pallet pickup and drop-off, we can create a solution that works effectively in simple and moderately complex situations, reducing processing time and resource usage.

For optimizing paths, various approaches exist. Path optimization can be approached mathematically using Jacobians, which map control inputs, like position or wheel speeds, to the desired outcomes. The objective is to minimize a cost function—such as path length, energy use, or time—by adjusting the robot’s control inputs to achieve the desired position. A common technique is gradient descent, where control inputs are iteratively updated to reduce the cost. The Jacobian matrix, which links these inputs to the robot’s position, guides these adjustments until the most efficient path is found. However, the Jacobian-based optimization method poses several challenges for this use case. For wheeled mobile robots with multiple control inputs, the Jacobian matrix can become complex and large, leading to increased computational costs and making real-time optimization challenging.

Frequent updates in dynamic environments further add to this load, potentially leading to delays or suboptimal paths. Mukherjee et al. [44] noted that their approach to optimal trajectory planning does not guarantee a global optimum but rather an isolated local optimum close to the global one. Additionally, this method relies on precise kinematic and dynamic models, so any inaccuracies, such as sensor errors, can result in poor path optimization. In this context, the kinematic model would need to be refined for the specific truck using it. Managing complex inequality constraints, like obstacle avoidance, can also complicate the optimization process and reduce efficiency.

Reinforcement Learning (RL) offers a promising approach to learning optimal paths for mobile robots. By interacting with the environment and maximizing rewards, RL agents can develop effective policies. However, RL methods for path planning in wheeled mobile robots face significant challenges, including high computational costs, long training times, and the need for extensive data. These limitations make RL impractical for real-time applications in complex environments.

As highlighted in the previous Section , meta-heuristic approaches, though powerful for solving complex problems, often require significant computational time. However, this can be greatly reduced by optimizing how these methods are applied. Instead of generating a path entirely from scratch, this work proposes starting with a pre-built or partially constructed path provides a solid foundation. Additionally, reducing the number of waypoints can streamline computation, allowing the algorithm to focus on refining an already good solution rather than calculating every detail from the ground up. This approach preserves the strengths of meta-heuristics while significantly speeding up the planning process, making it more practical for real-time or near-real-time applications.

Conclusion

In this chapter a detailed State of the Art related to Intralogistics, AMRs, Near-Field Planning, and Heuristic Optimization was laid out. The investigation of the literature helped to address the advantages and limitations of individual approaches and decide around the relevant approaches to the Problem Statement. A Choice of the methodology was conducted at the end taking into account the compiled information. In the following chapter, we will delve into the design and development of the solution combining a Path generating to Metaheuristic Optimization to obtain an optimal path.

Chapter 3

Design and Development of the Proposed Solution

Chapter 3

Design and Development of the Proposed Solution

Introduction

This chapter details the design and development of the proposed path planning solution for logistics forklifts. The focus is on linking the robot to a pallet in the tight stations of a warehouse as a last maneuver to the pickup/drop process. The system uses pattern-based paths, elevated by meta-heuristic algorithms, to navigate efficiently in these confined areas. The chapter begins with an overview of the goals and the work structure, followed by an outline of the development steps used to ensure smooth and accurate movement toward the pallet. Implementation details are then covered, showing how the system components are integrated into a cohesive solution for precise pallet access within the warehouse environment.

1 | Conceptual Framework

1.1 Goal Setting

As mentioned in the introduction, this project does not tackle the navigation system of the AMRs in general, but is focusing on a specific movement that the AMR must perform in order to accurately dock the pallet/shelf. More details are explained in chapter 1, section 2. Considered the

problems detailed in chapter 1 and the state of the art outputs in chapter 2, the following goals were identified based on the former detailed requirements for applications to autonomous mobile robots in intralogistics:

- **Predictability and Robustness of Mobile Robot Behavior:** The solution we propose utilizes an intelligent approach to connect the robot to its destination. The developed algorithm generates an explainable navigation process that enables humans to understand and trust the technology. Additionally, secure decision-making for autonomous trucks is ensured by the developers.
- **Accuracy of the solution and station relation:** The developed solution has to be stable, repeatable and flexible: this means that it would work for almost all stations in warehouses where it operates. The linking to the destination is accurate and precise to avoid failures. Precision and accuracy are guaranteed by the fact that the planning is done in the limited station space: a narrow field that allows short distance perception and planning. The solution is then tailored to each environment's specificities.
- **Optimization of paths:** The algorithm optimizes the path by minimizing travel distance, reducing sudden turns, and avoiding challenging maneuvers that could strain the truck. This optimization ensures the most efficient route, balancing speed and safety. The approach is designed to be computationally efficient, allowing for real-time adjustments and smooth behavior of the autonomous truck.
- **Obstacle avoidance:** The vehicle avoids collisions and drives safely to its destination. The system is designed to prioritize safety while maintaining an efficient and effective route to the target location.

1.2 Development Methodology

To achieve the aforementioned goals, the design will follow a structured approach, consisting of the following key development steps:

- **Station Layout Analysis:** An analysis of the station layout enhances the development of station-specific solution. The analysis considers the differences in the stations dimensions and configurations and the solution is created in station relation to ensure precision and accuracy to potential changes like shelf shifts and unknown obstacles (obstacles that do not initially belong to the station). Understanding station layouts can improve path optimization, reduce the need for frequent replanning, and enhance the overall efficiency of operations.

- Path Generation: A robust and efficient path generation algorithm is developed and tailored to the station environment. The path follows human-driving patterns along with specific rules and constraints which enhances efficiency, predictability and makes use of explainable AI concepts.
- Path Optimization: Metaheuristic Algorithms are tested in different station configuration scenarios and discriminated. The most suitable algorithm in terms of processing time is considered. The optimizer generates an optimum path for specific criteria.
- Obstacle Avoidance: obstacles are avoided using the pattern path and optimizer constraints.

To overcome the drawbacks of the methods in Chapter 2, Our approach focuses on:

- Repeatability: by generating pattern based paths, the AMR's behavior is explainable at the linking phase: the AMR uses the pattern to create optimized trajectories and takes into consideration the environmental input. The simplicity of the approach makes it require a minimum amount of information and computational power.
- Operational Reliability: Tailoring the solution to the station and acquiring real-time sensor data about the target's location guarantees accurate path generation, as the generation of the path is processed according to real-world data instead of model data. This approach enhances task success rates and reduces path length due to the confined station environment.
- Computational Optimization: The approach uses Metaheuristic Optimization approaches to refine and discriminate already created paths using the pattern instead of building the path from scratch using the optimizer. This significantly improves computational efficiency.
- Kinematic constraints: The approach takes into consideration the volume of the truck and its constraints like reduced speed at highly curved areas and when direction changes are needed. The pattern-based approach further restricts directional changes, ensuring adherence to kinematic constraints and optimizing path generation.

The following sections will detail the design approach. Then, the implementation steps are explicated and demonstrated from the simulation point of view. Finally, the tests results are explained and discussed and the outlooks are elaborated.

2 | Methodology and Design of the Solution

Starting with the operating environment, the stations, the focus was on the problems inside. The issue of linking the forklifts in the near-field to the pallet is nothing but new to the intralogistics sector. The process is repeated dozens of times daily inside warehouses and factories where forklift drivers take control over resolving the problem. Taking a deeper look at their approaches to resolve the same issue, the autonomous vehicles team noticed that forklift drivers have certain driving styles that are repeated according to the current situation. Similarly to car parking, depending on the type of the parking slot, there are some patterns to reproduce in order to fit the car inside its assigned spot as given by figure 3.1. Each situation has an according pattern that is relevant to the car's orientation, the parking slot, and the direction of parking. The parking styles were set to teach beginners the way to park a car smoothly: stopping and changing directions are minimized by the shape of the path. The path is smooth and designed in a way to make steering possible online for instance in angle and perpendicular parking. For, Parallel and Perpendicular Back Parking, direction changes are needed to put the vehicle in a position where it can smoothly steer and rejoin the parking slot. The Perpendicular Back Parking is very similar to the forklift in the station case. The car arrives in main driving direction but needs to dock the slot in a backward direction. The parking pattern has 2 maneuvers: a first maneuver of direction change and a second maneuver of placing the car inside its slot. In these cases, the driver needs enough space for direction changing. To do so, he drives further to the opposite direction to allow the car to comfortably and smoothly drive to its parking place while steering gradually to correct the orientation. Parking assistance feature is embedded in human-driven and driverless cars to instill safety and order.

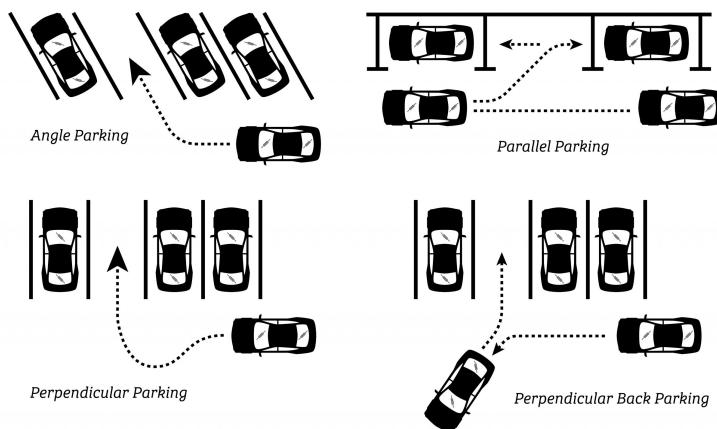

Figure 3.1: The Possible Parking Styles that a driver can follow

Analogically, after the truck arrives in the station, the drivers would drive and steer in the opposite direction of the pallet, until the forks are in a position to allow the truck to easily and correctly drive to the pallet in fork direction. The goal here is to develop a pallet-linking algorithm to automate the driving to the pallet pickup location for autonomous forklifts as given by figure 3.2. The truck would autonomously plan the path to its destination based on the pattern: the Station linking trajectory on figure 3.2 and on the environment settings that it would navigate in. The pattern enhances the explainability in the forklifts behavior. Explainability allows for more order in the warehouse: it simplifies the coordination of safe simultaneous tasks around the truck. This is achieved through the design of an algorithm that aims to create a transparent navigation process, making it easier for humans to understand and trust the technology. Additionally, the approach is intended to ensure secure and reliable decision-making for autonomous trucks.

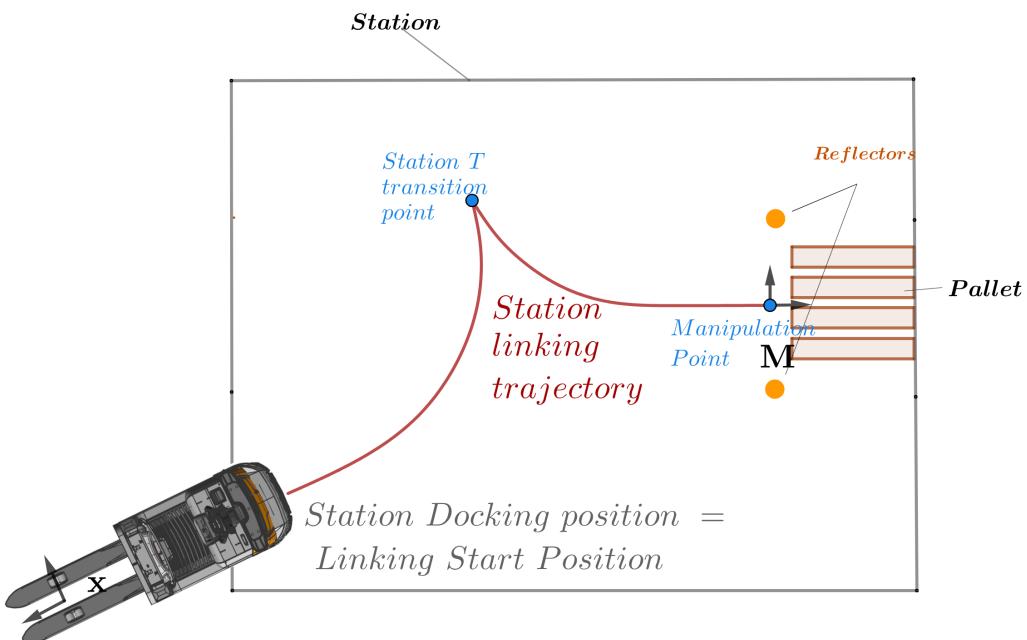

Figure 3.2: Design of Linking the robot to goal destination [28]

For the forklifts use case, the AMR enters the station in "Opposite Direction" and docks the shelf/pallet in "Main Direction" similarly to the Back Perpendicular Parking. From now on, the following definitions of driving directions will be used as given by figure 3.3:

- Main Driving Direction: Driving in fork direction.
- Opposite Driving Direction: Driving in vehicle chassis direction.

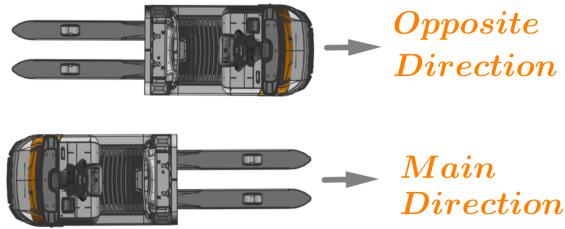

Figure 3.3: Truck Driving Directions

The designed approach is illustrated in figure 3.5. The following transition method is proposed: Once the AMR docks the station, it has the option to transition and change direction on the sides of the shelf placed inside the station. First, it drives to the transition position, then, to the pallet or the drop-off position as given by figure 3.4. Having two possibilities for transition zones allows for more flexibility: in case one area is unreachable or presents obstacles, the second one can be used. They present free areas inside the stations where less obstacles and dynamics are expected and smooth maneuvering of the truck can be managed. In addition, the geometric solution is scalable to any station that is recognized and whose properties are available to the truck. This makes the overall solution and the autonomous forklifts simple to commission in new warehouses.

Smooth and continuous paths are generated through spline interpolation of constructed waypoints (see section 3.2.2). This technique ensures that the resulting paths are smooth, operationally seamless, and reduce abrupt changes in direction and speed. By interpolating between waypoints, the method enables the creation of curves that are optimized for driving efficiency and stability.

Finally, an optimizer generates multiple path candidates and rigorously evaluates each one based on key factors. The evaluation considers the path's length, smoothness, and potential collisions with surrounding objects to ensure the chosen path is both efficient and safe. After testing all options, the path that best meets these criteria—providing the shortest and smoothest route with minimal collision risk—is selected as the best solution following Evaluation methods explained more in section 3.3.

This approach ensures the final path is not only theoretically ideal but also practical and reliable for real-world use. The process is designed to be flexible and effective, even in obstacle environments. The designed methodology is summarized in the following flowchart 3.5:

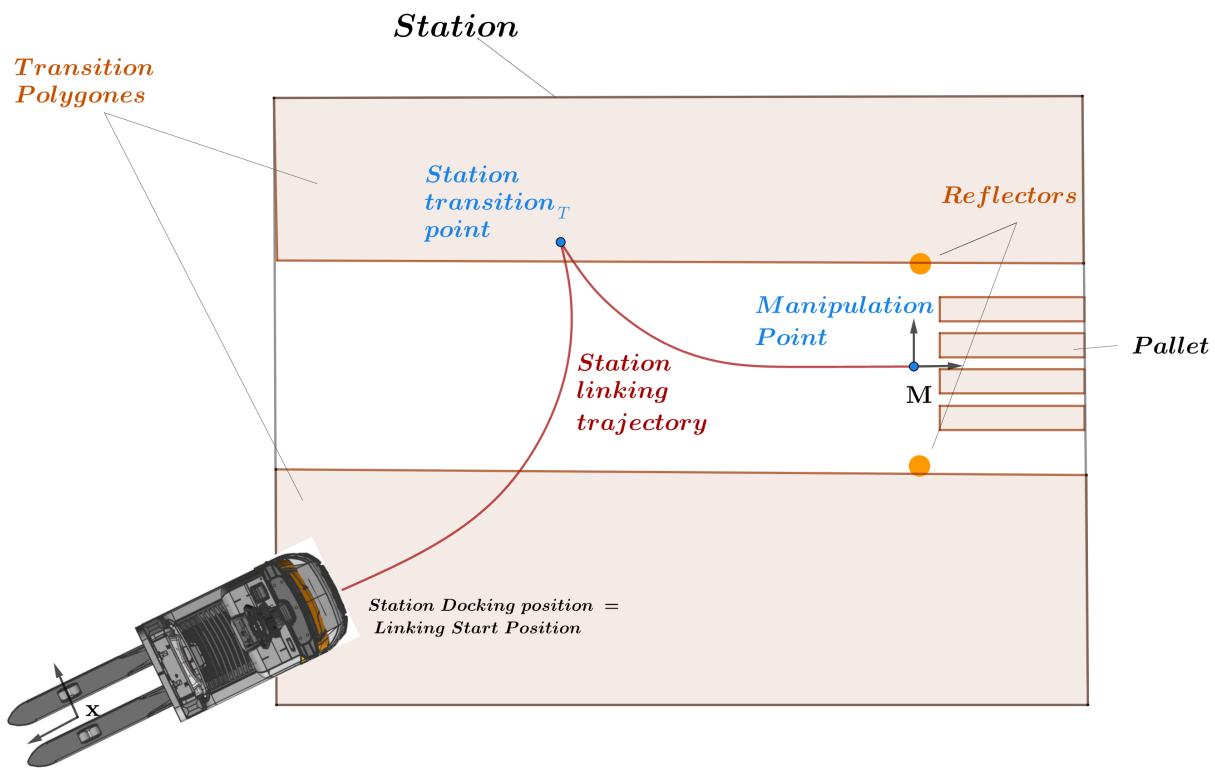

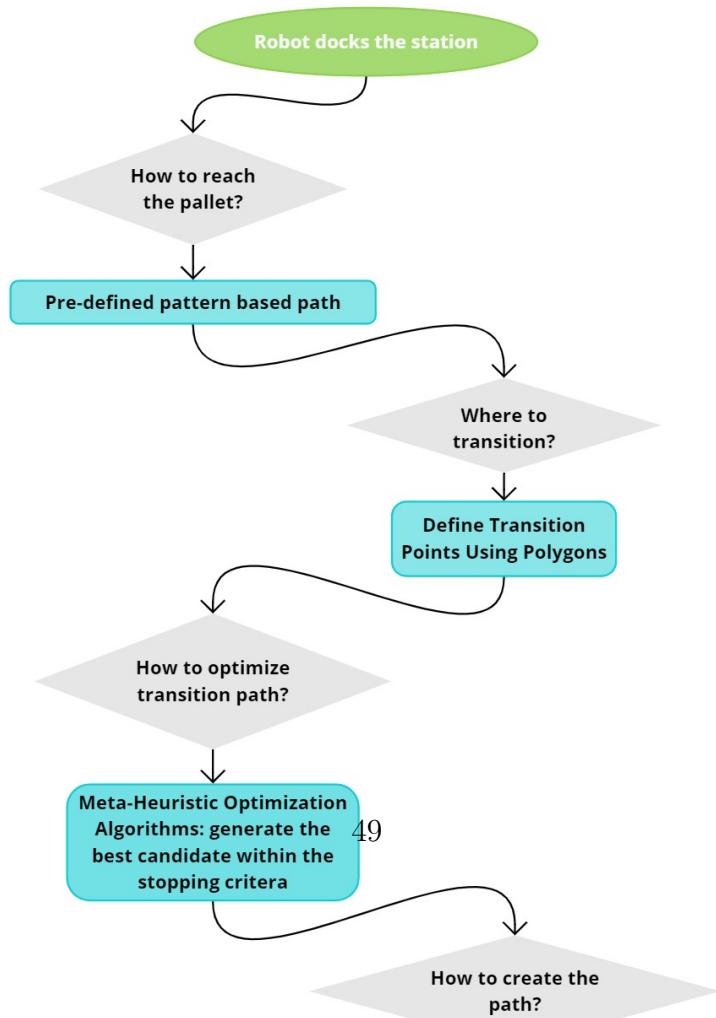

Figure 3.4: Step1: Station Partitioning for Linking the robot to goal pallet [28]

3 | Development phases and Implementation

This section details the rollout of the module development, providing a comprehensive overview of the process. It is structured to include both the development steps and the corresponding simulation results at each phase. Every phase started with a deep investigation of the existing relevant solutions detailed in Chapter 2.

3.1 Geometric Partitioning of the Station

This section explains the development of the geometric Partitioning of the station into 2 polygons used later for transitioning inside the station. **The input of this step is the station information and the output are the polygons.** As explained previously in Section 3.2, in order to carry out the transitioning of the vehicle inside the station to change the driving direction from the opposite to the main direction, Transition subpolygons are needed. The subpolygons are created according to the station shape and dimensions and the position of the shelf inside of it. As given by figure 3.7, the stations can be found at certain positions of the warehouse.

3.1.1 Implementation of the Station Partitioning

The vehicle initially plans its missions: it constructs a plan of the stations that will be visited and the operations to do on each station. While the path driven from one station to the other is pre-defined by the global planner, the path linking the vehicle to the pallet is to be planned in real-time. Once the vehicle arrives at the docking position in the stations, it starts the path planning process. The station-related information are stored in a file accessible to the vehicle. These information include stations' positions and dimensions and the coordinates of the shelf that it contains. For each station represented like figure 3.6 the module creates the subpolygons on each side of the shelf, limited by the station and shelf shapes.

The process that creates the subpolygons is detailed in the following Algorithm 1. The algorithm begins with an initialization step, then the corners of the station and shelf areas are retrieved and transformation matrices are prepared to convert coordinates between global and shelf-specific coordinate systems. The need to transform the used coordinates to the shelf frame is derived from the scalability needs. As seen on figure 3.7, stations can be placed in different positions and have different orientations. If global coordinates are used, it becomes computationally challenging to develop an exhaustive algorithm that fits all the possibilities of station orientation and shelf configurations. On

the other hand, using the shelf coordinate frame shifts the point of view to the inside of the station only. It enables the shelf to orchestrate the geometric partitioning of the station based on its position in the station.

The transformation matrix from the shelf to Global is illustrated in figure 3.6.

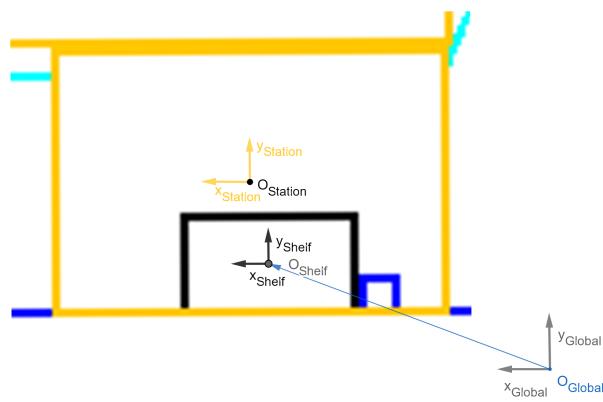

Figure 3.6: Station Simulation with added Station, Shelf, and Global (World) frames

It is measured as follows:

$$T_{\text{Shelf}}^{\text{Global}} = \begin{pmatrix} \cos(\theta) & -\sin(\theta) & t_x \\ \sin(\theta) & \cos(\theta) & t_y \\ 0 & 0 & 1 \end{pmatrix} \quad (3.1)$$

Where:

θ is the rotation angle between the shelf and global frames.

t_x and t_y are the translation components along the x and y axes, respectively.

Now, the inverse transformation that will be used to change the coordinates from the global frame to the shelf frame is:

$$T_{Global}^{Shelf} = (T_{Shelf}^{Global})^{-1} \quad (3.2)$$

The algorithm then iteratively transforms the station and shelf corners from global coordinates to shelf coordinates, storing the transformed corners in dedicated lists. The mathematical equation behind this transformation can be expressed as:

$$\begin{pmatrix} x_{shelf} \\ y_{shelf} \\ 1 \end{pmatrix} = T_{Global}^{Shelf} \begin{pmatrix} x_{global} \\ y_{global} \\ 1 \end{pmatrix} \quad (3.3)$$

Where:

$$\begin{pmatrix} x_{shelf} \\ y_{shelf} \\ 1 \end{pmatrix} \quad (3.4)$$

is the transformed point in the shelf frame

$$\begin{pmatrix} x_{global} \\ y_{global} \\ 1 \end{pmatrix} \quad (3.5)$$

is the original point in the Global (World) frame

After the transformation, two subpolygons are created: one representing the Negative Y Sub-polygon (Negative Y of the robot-related frame) ,(NegYsub_polygon) and the other representing the Positive Y Subpolygon (Positive Y of the robot-related frame) (PosYsub_polygon). The subpolygons are data structures recognized by their global position and dimensions.

Definitions:

- $x_{station}^{\max}$: Maximum x-coordinate of the station corners in the station frame.
- y_{shelf}^{\min} : Minimum y-coordinate of the shelf corners in the shelf frame.
- $\text{width}_{\text{SubPolygon}}$: Width of the subpolygon (previously measured).
- $\text{height}_{\text{SubPolygon}}$: Height of the subpolygon (previously measured).

The position of the sub-polygon is thus measured:

$$x_{\text{SubPolygon}} = x_{\text{shelf}}^{\max} + \frac{\text{width}_{\text{SubPolygon}}}{2} \quad (3.6)$$

$$y_{\text{SubPolygon}} = y_{\text{shelf}}^{\min} + \frac{\text{height}_{\text{SubPolygon}}}{2} \quad (3.7)$$

Then the subpolygon is transformed back to the global frame using the Transformation Matrix 3.1:

$$\begin{pmatrix} x_{\text{GlobalSubPolygon}} \\ y_{\text{GlobalSubPolygon}} \\ 1 \end{pmatrix} = T_{\text{shelf}}^{\text{Global}} \begin{pmatrix} x_{\text{SubPolygon}} \\ y_{\text{SubPolygon}} \\ 1 \end{pmatrix} \quad (3.8)$$

For special cases like station3, where one of the subpolygons can be very narrow (lower than a certain threshold), the algorithm omits it and generates only one subpolygon. The algorithm concludes by returning the created subpolygon(s), effectively segmenting the input areas into distinct, usable geometric entities. The Pseudocode of the General Algorithm is given in Algorithm 1

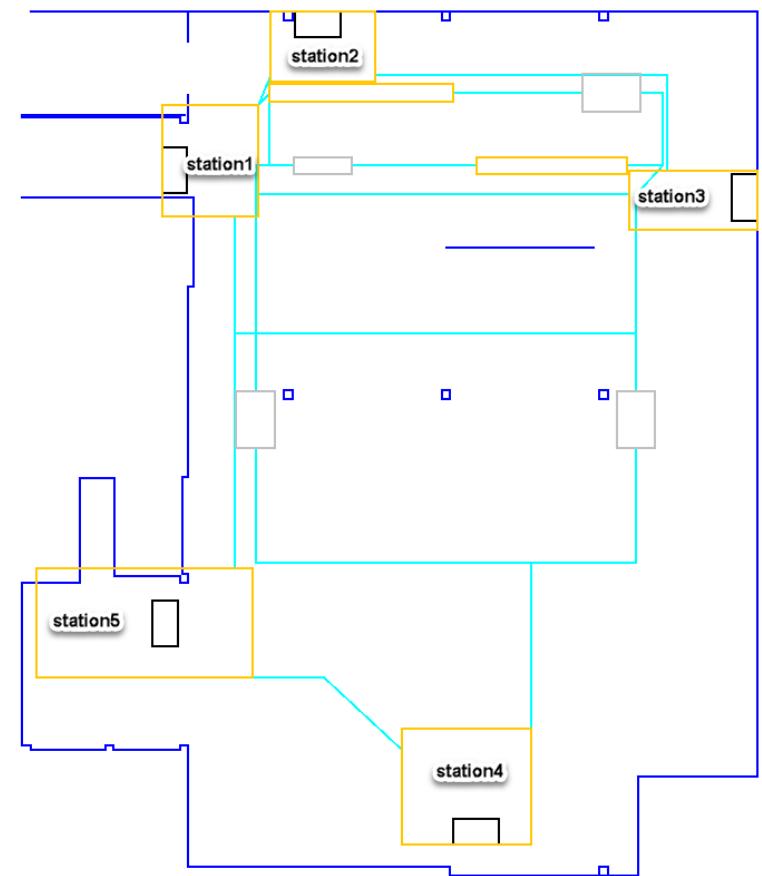

Figure 3.7: Simulation of the stations in a warehouse

The colored elements in this figure are explained here:

- Dark Blue outline: walls of the warehouse
- Yellow Rectangles marked as stations: Warehouse stations: Actions like picking up or dropping are performed in specific locations inside the warehouse called stations, examples of which are named *station1*, *station2*, and *station3* on the figure 1.8. Each station is designed to support specific warehouse functions and their general mission is to facilitate and organize material handling operations. Each station contains a **shelf** that contains the pallets to be picked or dropped.
- Black rectangles: storage shelves (also called racks), where the pallets and material are stored.
- Turquoise blue lines: Global paths that connect the stations. The truck takes these routes when navigating from a station to the other while avoiding obstacles online if they occur.

- Gray rectangles are starting position of the truck around the warehouse. For instance, the truck can be placed at these positions before starting its autonomous navigation and task fulfillment.

Algorithm 1: Creation of Subpolygons

Data: station_area, shelf_area

Result: created two subpolygons

```

1 Initialization;
2 station_corners, shelf_corners  $\leftarrow$  GetCorners(station_area, shelf_area);
3 tm_station_corners, tm_shelf_corners  $\leftarrow$  empty lists;
4 tm_shelf2global  $\leftarrow$  GetTransMatrix(shelf_area);
5 tm_global2shelf  $\leftarrow$  InvertMatrix(tm_shelf2global);
6 foreach corner  $\in$  station_corners do
7   corner_shelf  $\leftarrow$  TransformCorner(tm_global2shelf, corner);
8   tm_station_corners.append(corner_shelf);
9 station_corners_shelf.append(tm_station_corners[0]);
10 foreach corner  $\in$  shelf_corners do
11   corner_shelf  $\leftarrow$  TransformCorner(tm_global2shelf, corner);
12   tm_shelf_corners.append(corner_shelf);
13 NegYsub_subpolygon  $\leftarrow$  CreateNegYsubpolygon(tm_station_corners, tm_shelf_corners,
    tm_shelf2global);
14 PosYsub_subpolygon  $\leftarrow$  CreatePosYsubpolygon(tm_station_corners, tm_shelf_corners,
    tm_shelf2global);
15 return created two subpolygons;
```

3.1.2 Results of the Station Partitioning

In figure 3.8 stands the simulated result processed using real station data: In purple and orange are the polygons, and in green the outer polygon represenst the station. The station used is the Station *EmptyPallets* of the warehouse.

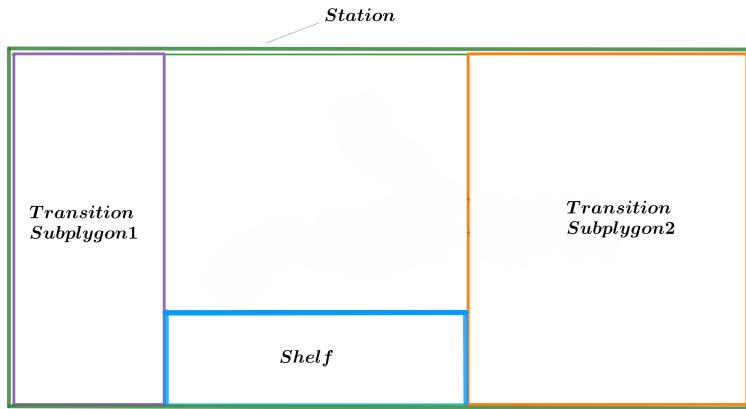

Figure 3.8: Partitioning: Station divided into subpolygons

3.2 Path creation

This section details the methodology for path creation. **The input of this section are the polygons besides the robot's position and the destination. The output is a spline-based path linking the robot to the destination with a driving direction change.**

3.2.1 Choice of Path Creation Methodology

The pattern path links the AMR at the start position to the transition position on the subpolygon then to the destination point as illustrated in figure 3.2. The waypoints depicted on the simulation figure 3.9 are created relating to the Robot, the destination and the transition positions. In a simple scenario where no obstacles are present, orientation points are strategically added in front of the three key positions of the robot. These orientation points serve as reference markers that guide the robot's movement, particularly during the initial phase of acceleration or deceleration. When the robot starts to move, it follows a precise trajectory, either in a straightforward or straight-backward direction, depending on the intended driving direction. This straight-line motion ensures that the robot maintains stability and accuracy as it transitions from a stationary position to motion or vice versa, minimizing any unnecessary deviations or turns that could disrupt its path. The alignment with the orientation points helps the robot to consistently maintain a straight trajectory, which is crucial for precise navigation and control.

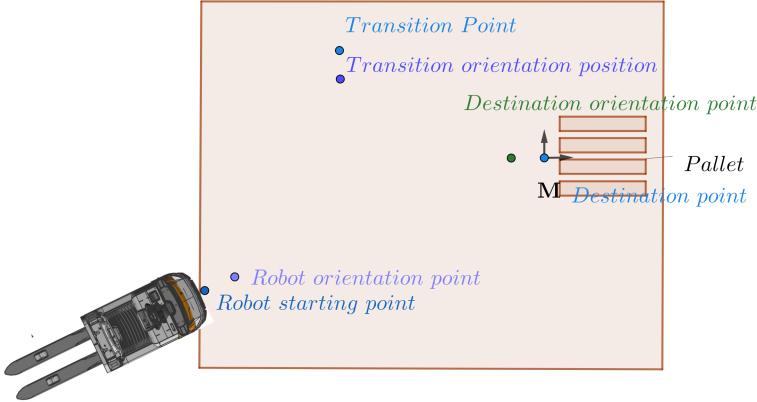

Figure 3.9: Step2: Orientation Points creation using the 3 origin path points

The waypoints are then connected to form the path. However, to obtain smooth paths there should be curved paths that connect waypoints seamlessly instead of simple vertices connection.

Spline-based paths provide several key benefits for robotic navigation. They ensure smooth and continuous movement by creating curved paths that connect waypoints seamlessly. Unlike abrupt turns and sharply angled paths, this smoothness reduces wear on the robot and makes its movements more energy-efficient. Additionally, spline-based paths make it easier to control the robot in real-time, allowing for quick adjustments if the environment changes and preventing oscillations as a response to control corrections. Using mathematical equations to define these paths also makes it simple to calculate important properties like path length and curvature, helping the robot navigate efficiently and safely.

3.2.2 Spline Based Paths

3.2.2.1 Splines Applications in Robotics

Robots like AMRs in the intralogistics sector usually have mission to carry heavy loads. This property makes it risky to operate abrupt motion changes like stopping or turning. These vehicles' motion planning requires precise control and detailed alignment to the kinematic constraints that they present [30]. Given the mathematical nature of Splines, namely B-splines they ensure continuity of the first and second derivatives. This continuity translates to smooth transitions of the resulting

velocities and accelerations of the path that the robot will follow. By having continuous velocity and acceleration, we make sure that the robot achieves smooth transitions and speed changes. Furthermore, tracking, precise following and correct control interventions are guaranteed allowing for precise navigation [30].

Although simple, the connected waypoints approach comes with drawbacks like sub-optimal travel time, unoptimized long paths, and mechanical wear because of abrupt direction changes unlike curved paths [30]. The morphological difference in both paths is distinguished in figure 3.10. On the reader's left is a path of consequent vertices. This path has corner shaped turns which are rough to navigate for AMRs. The vehicle has to stop at the corner before taking the next vertex as the change in direction happens suddenly and not gradually. On the right, the path is a curve controlled by the positions of the waypoints. The change in direction happens gradually and the navigation on this route is smoother than the previous.

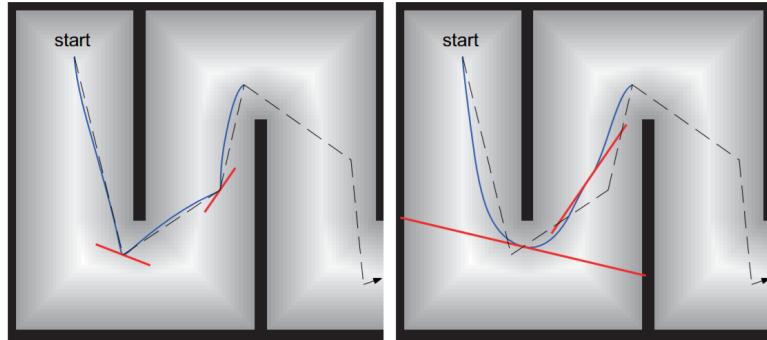

Figure 3.10: Morphological difference between a path connecting waypoints (left) and a curved path (right) [30]

Multiple approaches have been developed to introduce smooth transitions and turns into robot trajectories. One such method involves using Clothoid curves, which connect straight path segments with circular arcs to avoid abrupt changes in direction [31]. Originally introduced for designing highways and roads to ensure safe and comfortable driving for humans, Clothoids offer a gradual change in curvature.

However, when applied to robotics, Clothoid curves present certain drawbacks. These include the potential for discontinuities in curvature at the transitions, which can lead to jerky motions in robotic paths. Additionally, Clothoid-based paths can result in sub-optimal path lengths, as they may not be the shortest possible routes. Moreover, while circular arcs with constant radii are used in this approach, long arcs lead to large curvatures, and can lead to loss of control and instability of the AMR , which can be impractical for mobile robots that require tighter turns and more precise control [31].

Migrating from a path with sharp angles to one with smooth curves can be effectively accomplished by using splines. The interpolation of the control points of the original path creates a smooth, continuous curve. By incorporating a convex hull around these control points, we ensure that the path does not deviate excessively from the desired points, thus avoiding potential collisions with obstacles [33]. The convex hull acts as a boundary that keeps the spline inside the limits of the control points that parametrize it (see figure 3.11) and keeps the robot from straying too far, ensuring a safe and accurate trajectory [29].

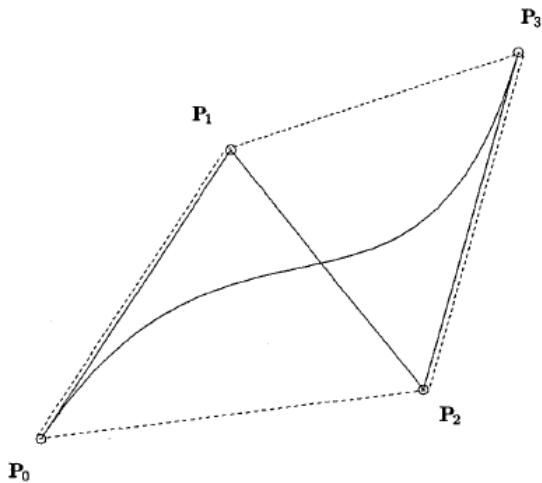

Figure 3.11: Convex hull contained Spline [29]

Splines are advantageous because they can accommodate various constraints such as curvature limits and minimum turning radii. These constraints are crucial in many applications, including robotics and vehicle navigation, where maintaining a smooth path is essential for stability and control. By adjusting the spline parameters, it is possible to design paths that meet specific requirements, ensuring that the resulting trajectory is not only smooth but also feasible given the physical and operational constraints [30].

In scenarios involving obstacle avoidance, splines can be blended or connected to create a seamless path while circumventing obstacles. This blending technique allows for the integration of different spline segments into a continuous trajectory, ensuring that the path remains clear of obstacles. By carefully adjusting the blend points and ensuring smooth transitions between splines, it is possible to navigate complex environments safely and efficiently. This approach combines the advantages of smooth path planning with effective obstacle avoidance.

A notable case study of splines integration in solving path planning problems, is a research conducted by B. Lau et al. [30] that aims to develop a time optimal solution while considering the

kinodynamic properties of a mobile robot. They used a global planner to generate straight-line paths and minimize time of travel. Then, they integrated splines to join the resulting path segments in a smooth and continuous way and replan in case of unprecedented collisions. The results show that our motion planning system works well in both real and simulated settings. It created smooth and accurate paths, with an average positional error of about 1 cm and a velocity error of less than 2 cm/s. The optimization process improved travel time by 31% compared to initial paths. The system also handled dynamic environments, like crowded trade shows, and adjusted smoothly when localization errors occurred by updating the path as needed. Overall, it performed reliably, navigating precisely and adapting effectively to changes and errors.

In general, Splines are an effective tool that centralizes advantages related to path smoothness, simplicity of constraining the path according to the kinodynamic properties and mechanical limitations of the mobile robot like limiting the curvature, and allowing for safe and smooth speed and direction changes. These properties accommodate simple manipulation of splines for path planning and tracking of path properties. As an illustration, it is possible to measure the spline's features like curvature or approximate its length.

3.2.2.2 Splines Mathematical concepts

In mathematics and computer graphics, a **curve** is a continuous and smooth flowing line without sharp angles ???. It can be defined parametrically or implicitly and represents a path that can be traced by a moving point. A curve can be defined using a parameter u , where u varies over an interval, and the coordinates of the curve are given by functions of:

$$C(u) = (x(u), y(u)) \quad \text{given} \quad a \leq u \leq b \quad (3.9)$$

The circle is an example of a curve where:

$$x(u) = \cos(u) \quad (3.10)$$

$$y(u) = \sin(u) \quad \text{given} \quad 0 \leq u \leq \frac{\pi}{2} [29] \quad (3.11)$$

whereas, the implicit form of the circle would be:

$$(x - h)^2 + (y - k)^2 = r^2 \quad (3.12)$$

where (h, k) is the center and r is the radius.

Parametric curves have a clear direction (from C(a) to C(b)), which implicit curves lack. This makes it simpler to create ordered sequences of points along a parametric curve. Additionally, the parametric form is more intuitive for designing and modeling shapes on a computer, as the coefficients in many parametric functions (such as Bezier and B-Splines) carry geometric significance. This results in user-friendly design techniques and algorithms that are numerically stable [28]. However, using one polynome-curves is inadequate as it is not possible to represent complex shapes, certain curve changes, and fitting the needed points. The solution is to use piecewise polynomial curves of degree $(n - 1)$ for example if we need to integrate n data points [29].

Polynomials are a commonly used type of function in robotics because they can be easily differentiated and are less prone to numerical rounding errors (known as floating point errors). Although they cannot represent every geometric curve, polynomials can usually approximate them with sufficient accuracy.

Using classical polynomial functions or their derivatives in Bézier form is mathematically equivalent. This means that any curve described using standard polynomials can be transformed into a Bézier curve, and vice versa. However, when it comes to geometric modeling—especially in applications like computer graphics or robotics—the Bézier form is often preferred. This preference is due to the fact that the coefficients in the standard polynomial form (also known as the power basis form) don't offer much information about the curve's actual shape, making it harder to intuitively control and adjust the curve. In contrast, the coefficients in the Bézier form -the control points- directly influence the shape of the curve, in a visually meaningful way, making it easier to understand and manipulate as shown in equation 3.13 [28].

$$C(u) = \sum_{i=0}^n B_{i,n}(u) \mathbf{P}_i \quad \text{with } 0 \leq u \leq 1 \quad (3.13)$$

The basis function $B_{i,n}(u)$ is called the Bernstein polynomial of degree n and follows the equation

$$B_{i,n}(u) = \frac{n!}{i!(n-i)!} \cdot u^i \cdot (1-u)^{n-i} \quad (3.14)$$

In this context, the Bernstein polynomial is a fundamental component. The basis function $B_{i,n}(u)$ is used to determine how much influence each control point \mathbf{P}_i has on the shape of the Bézier curve.

The geometric coefficients \mathbf{P}_i are known as control points, and they define the shape of the polynomial curve. In many applications, such as mapping trajectories, a large number of control

points is needed [28]. Furthermore, in the Bézier form, the continuity of the curve depends on the placement of control points. This means if you want to change the shape of part of the curve while keeping the rest smooth, you can't easily do so because changing one part affects the whole curve [29].

Instead, a more effective curve representation can be expressed as:

$$C(u) = \sum_{i=0}^n N_i(u) \mathbf{P}_i \quad (3.15)$$

where:

- \mathbf{P}_i : the control points
- $N_i(u)$: the piecewise polynomial functions

The continuity of the curve is determined by these basis functions, allowing for flexible modification of control points without affecting the curve's smoothness [29].

The basis functions for B-splines are defined recursively. For a given degree p and a set of non-decreasing knot values $\{u_i\}$, the basis functions $N_{i,p}(u)$ can be defined as:

$$N_{i,0}(u) = \begin{cases} 1 & \text{if } u_i \leq u < u_{i+1} \\ 0 & \text{otherwise} \end{cases} \quad (3.16)$$

$$N_{i,p}(u) = \frac{u - u_i}{u_{i+p} - u_i} N_{i,p-1}(u) + \frac{u_{i+p+1} - u}{u_{i+p+1} - u_{i+1}} N_{i+1,p-1}(u) \quad (3.17)$$

With:

- u is the parameter along the curve.
- u_i are the knot values, which divide the parameter range into intervals.
- $N_{i,p}(u)$ are the B-spline basis functions of degree p .

In figure 3.12 stands an example of a spline (Red Curve) generated through setting random control points (Green squares) using the NURBS generator [W1].

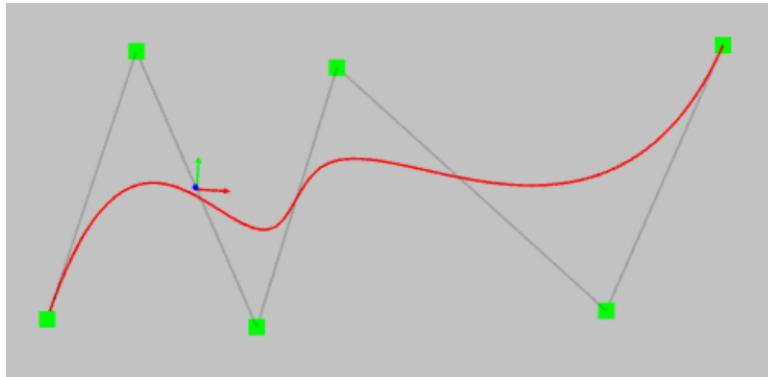

Figure 3.12: NURBS spline example.

Green: Control points
Red: NURBS spline

Due to their local control and numerical stability, B-splines are preferred over other spline types. This means that modifying a single control point only affects a localized portion of the curve, making them easier to manipulate and less prone to numerical errors. B-Splines will be used for the Creation of the paths for this work.

3.2.3 Implementation of the Pattern Path Creation Approach

Path creation comes after the creation of the subpolygons. After a transitioning point is chosen (see next section, Path optimization), the waypoints are created.

Then, the orientation points are interpolated to create the spline-based path. Given the need to create the driving direction change as a straight section of the path, two different splines will be interpolated using 4 waypoints each:

- The first spline interpolates the starting points then the transition points.
- The second spline interpolates the transition points then the destination points.

By doing so, two connected splines are obtained. Then they are merged together in the same path data structure to form one path. The first spline is driven in opposite direction driving, the second in main direction driving. The transition section at the polygon enables the robot to have an orientation that facilitates changing the driving direction as given by figure 3.14.

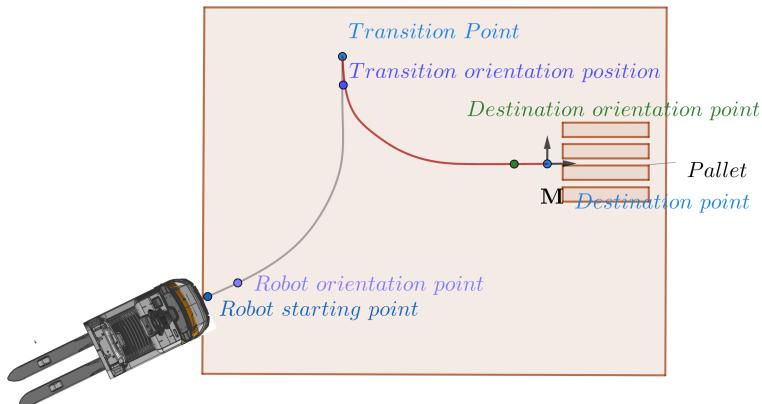

Figure 3.13: Step3: Interpolation of the waypoints and creation of the spline-based paths

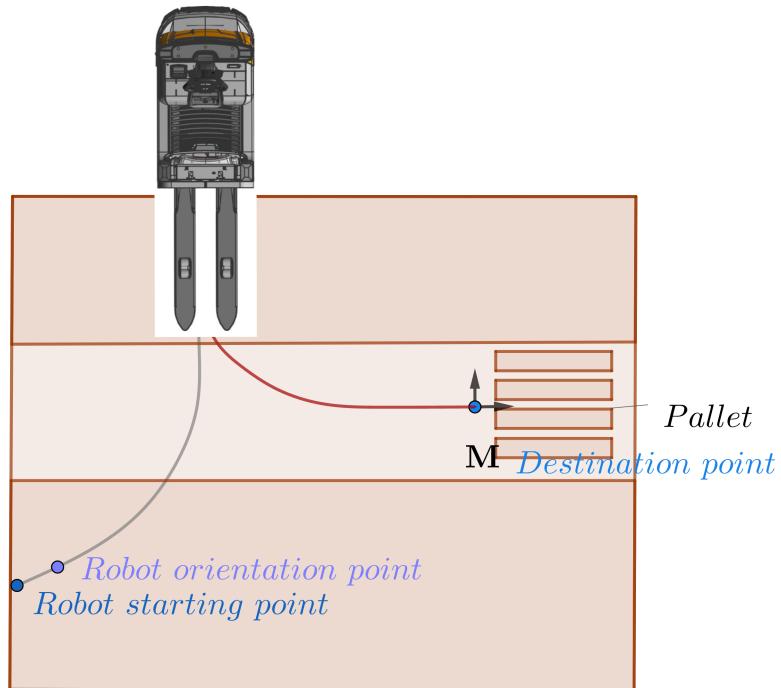

Figure 3.14: Robot at the transition position

The interpolation of the waypoints and the manipulation of splines is through The Spline Library integarted in the RACK framework (See RACK section). The library provides tools to construct

splines through several methods like interpolating points or blending two or more splines together and retrieve their features by segmenting the splines and calculating length and curvature for instance. The result is a structure of coordinates through which passes the spline. The Algorithm of the approach to create a spline is explained in Pseudo code 2. The algorithm first acquires the waypoints to be interpolated. Then it creates the curve and measures the minimum and maximum parameter values from the knot vector which are used to evaluate the curve but also to retrieve relevant data about the splines like positions. It guides the exploration of the spline. Besides, the spline length and cumulated curvature change are retrieved. The curvature change supervises the abrupt changes in curvature in segment curves of the whole spline. Finally a number of positions belonging to the spline is retrieved and transferred to the path data structure, this is where the resulting spline is transformed into a path that the robot can follow.

To fulfill the goal of path accuracy and precise docking of the target shelf or pallet, The path is created in the pallet frame. Once the AMR enters the station, it detects the shelf through the reflectors placed on the sides of the shelf marked in orange on figure 3.2, which allows for real and accurate detection of the shelf. The pallet location is known through the shelf properties. Then, transformation matrix are calculated using the reflectors positions in the robot ${}^{Robot}ReflectorPos$ and the pallet position in the Reflectors ${}^{Reflector}PalletPos$ to create the pattern path in the goal's frame: The transformation matrix can be expressed as:

$$T_{Robot}^{Pallet} = T_{Reflector}^{Pallet} \cdot T_{Robot}^{Reflector} \quad (3.18)$$

The transformation matrices and their inverses are represented as follows:

$$T_{Reflector}^{Pallet} = \left(T_{Pallet}^{Reflector} \right)^{-1} \quad (3.19)$$

$$T_{Robot}^{Reflector} = \left(T_{Reflector}^{Robot} \right)^{-1} \quad (3.20)$$

The transformation matrix from the pallet frame to the reflector frame is given by:

$$T_{Pallet}^{Reflector} = \begin{pmatrix} \cos(\alpha) & -\sin(\alpha) & Pallet_x^{Reflector} \\ \sin(\alpha) & \cos(\alpha) & Pallet_y^{Reflector} \\ 0 & 0 & 1 \end{pmatrix} \quad (3.21)$$

Similarly, the transformation matrix from the reflector frame to the robot frame is:

$$T_{Reflector}^{Robot} = \begin{pmatrix} \cos(\beta) & -\sin(\beta) & Reflector_x^{Robot} \\ \sin(\beta) & \cos(\beta) & Reflector_y^{Robot} \\ 0 & 0 & 1 \end{pmatrix} \quad (3.22)$$

Where:

- α is the orientation angle of $Pallet^{Reflector}$
- β is the orientation angle of $Reflector^{Robot}$

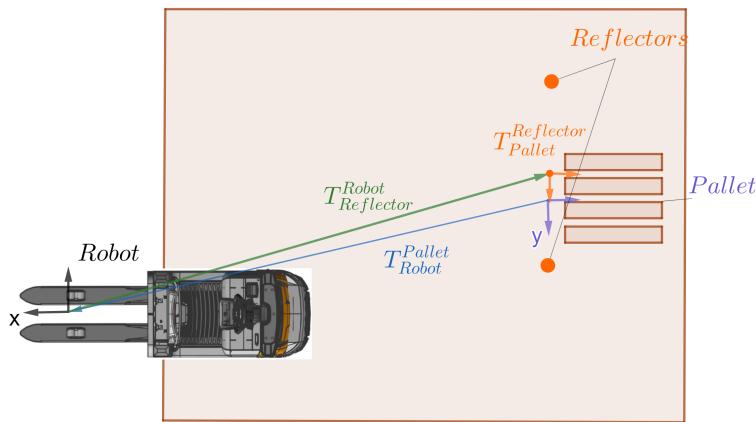

Figure 3.15: Transformations From the Robot to the Pallet Frame Passing by the Reflector Frame

The transformations between the different objects are illustrated by figure 3.15. **The Green Arrow** represents the Transformation from the Reflector to the Robot $T_{Reflector}^{Robot}$. **The Orange Arrow** represents the Transformation from the Pallet to the Reflector $T_{Pallet}^{Reflector}$. **The Blue Arrow** represents the Transformation from the Robot to the Pallet T_{Robot}^{Pallet} .

The general Pseudocode of the Path Generation is explained through Algorithm 2.

3.3 Path Evaluation

Once the path has been created and the relevant information has been retrieved, the foundation is set to evaluate the quality of the generated paths. **The input for this section is a spline-based path pattern, and the output is a scalar value that reflects the quality of the path.** Path evaluation allows to assess the quality of a path. From the vehicle's perspective, it enables the prediction of whether the path is mechanically and strategically feasible in terms of curves, sharp turns, direction changes, and other factors. This evaluation prevents the vehicle from following low-quality paths and paves the way towards optimization and selection of the best possible routes. The literature proposes several approaches to path evaluation that have been tested and assessed in this work.

3.3.1 Path Evaluation Techniques in Robotics

When planning paths for robots in the Intralogistics or in any field in general, it is important to have the ability to quantify the quality of the resulting path. There exists different ways to judge the efficiency of the solution and to which extent it accommodates the goal and optimizes the gaps

that we are willing to improve. This section studies the strategies that the literature followed while quantifying path quality in the robotics field. It will look at the different indicators, why, and in which case they were used.

3.3.1.1 Core Metrics for Path Evaluation

The key metrics that researchers focus on and try to improve can vary depending on the specific areas of optimization they are working on. For example, if the goal is to make a robot move faster, then time and speed might be the main metrics they study. On the other hand, if the focus is on making the robot navigate more safely, then the proximity to obstacles and collision avoidance would become the primary metrics. Therefore, the choice of metrics is closely linked to the particular goals that researchers aim to achieve in their optimization efforts.

According to Tang, S. H. et al. [20], from 2011 to 2015, the second most common topic in the path planning research scope was path length. Path length is a key metric that helps us understand other important factors like travel time and energy consumption. By measuring the length of a path, we can get insights into how long it will take to travel and how much energy the robot might use. In other words, path length often reflects the overall efficiency and effectiveness of the route. Heiden, E et al. [23], employed path length as one of the metrics used to evaluate the length of the paths generated by the algorithms they benchmarked. Their planners were configured to minimize path length, therefore, they measured the path lengths that were computed in 4 scenarios with applied to 17 path planners and 4 steering algorithms. They used path length, along other metrics, to quantify the quality of paths after planning and smoothing. Besides, they compared the algorithms using the above-mentioned metrics in order to classify them under the benchmark and to justify the choice of the best algorithm.

In addition to path length, Path smoothness is crucial for robotics in general and especially in the intralogistics sector because it directly affects the efficiency and safety of robot operations. Smooth paths reduce the need for sudden stops or sharp turns, which helps robots maintain a steady speed and avoid unnecessary wear on their components. In intralogistics, where robots often work in busy environments with other machines and human workers, smooth paths also minimize the risk of accidents and product damage. Overall, ensuring path smoothness helps robots operate more reliably and effectively, leading to faster and more accurate material handling. Path smoothness reflects less cusps -sharp turns- and generally less curvature which allows for smooth driving and smaller scale steering. Curvature of a circle at a point $x(t)$ is defined according to Gary D. Knott, in his book "Interpolating Cubic Splines" [34], as the reciprocal of the radius at the same point as shown in equation 3.23.

$$\kappa = \frac{1}{R} \quad (3.23)$$

For a cubic spline $y = f(x)$, the curvature κ at a point x is given by:

$$\kappa = \frac{|f''(x)|}{\left(1 + (f'(x))^2\right)^{3/2}} \quad (3.24)$$

Heiden, E et al. [23], also relied on curvature to determine path quality. They used it along path length and tracked it for the different scenarios and algorithms to measure their effectiveness. Liu, S. et al. integrated path smoothness metric to quantify path quality for their benchmark to compare motion planning algorithms[35]. Although the above-mentioned sources used the metrics to evaluate their optimized solutions, they did not mention the equations that they use to quantify those values.

Path clearance is another significant metric used to evaluate how well a robot can safely navigate its environment. It measures the distance between the robot's position along the path and any obstacles it might encounter. A larger path clearance means the robot has more space around it, reducing the risk of collisions and making the path safer. This metric is especially useful when optimizing paths, as it helps ensure that the robot can move smoothly without bumping into objects or other robots. Elshamli, A. et al. [17] have used path clearance as one of the indicators of path feasibility. Clearance is measured as follows in 3.25:

$$\sum_{i=1}^{n-2} \exp(a \cdot (g_i - \tau)) \quad (3.25)$$

where g_i is the shortest distance from the i^{th} discrete position of the robot to the surrounding obstacles, and τ is the desired clearance distance that guarantees safety. By focusing on path clearance, we can design routes that not only get the robot from one point to another efficiently but also do so in a way that minimizes risks and improves overall safety.

3.3.1.2 Combinations of single metrics

Some applications focus solely on minimizing path length. They use this single value as the metric for evaluating and distinguishing path solutions or for optimization. However, other applications require the combination of several metrics. Elshamli, A. et al. [17] used a weighted sum of the Distance between two nodes, or two waypoints, Path smoothness, and clearance as given by 3.26.

$$\text{eval}(p) = w_d \cdot \text{dist}(p) + w_s \cdot \text{smooth}(p) + w_c \cdot \text{clear}(p) \quad (3.26)$$

The outcome of this evaluation function of each path is used as the fitness function for that path. The fitness of each path serves later the evolution of the genetic algorithm.

Zhang B et al. [36], deployed a nonlinear optimization problem that integrates path length and curvature variation over a spline-based path. The problem is constrained by the curvature limits, the parametrized location of the spline's control points, and the distance to obstacles.

Combining metrics for path evaluation should be done with a simple approach. Using more metrics can make the optimization process complex and slow, as the optimizer has to handle more variables. Using too many metrics can lead to overfitting, where the model becomes overly sensitive to specific parameters and may not generalize well to new data. This can result in inconsistent results that may favor or neglect certain parameters in different situations.. By keeping the metrics to a manageable number, we ensure that the optimization remains efficient and the impact of each metric is clear and easy to interpret. Using a more metrics like computational time, number of cusps or direction changes, solvability percentage or predicted speed or travel time can be efficient for evaluating path planning algorithms and benchmarking some usecases as in [23].

3.3.2 Implementation of Path Evaluation Techniques

By analyzing the spline, key characteristics of the path can be determined, such as its length, curvature, and the time required to traverse it. The following requirements are essential for developing a robust path evaluation formula:

- The formula used to evaluate the path must be **simple** enough to be easily integrated into an optimization process. During path planning, optimization algorithms are often employed to find the best possible path according to certain criteria. These algorithms require objective functions that can be computed efficiently. A complex or computationally expensive formula may slow down the optimization process or make it impractical for real-time applications. Therefore, the path evaluation formula should be simple, allowing for quick calculations that can be repeatedly applied within an optimization loop. This simplicity also facilitates its integration with existing optimization frameworks.
- The formula should include a **normalization** step to ensure that different paths can be compared on a common scale. Paths can vary significantly in terms of length, curvature, and other characteristics. To make meaningful comparisons between paths, it's essential to normalize

these metrics. Normalization involves scaling the values of each metric (e.g., path length, curvature change) relative to a reference value, such as the characteristics of a potential ideal path. By normalizing the path metrics, it is ensured that the evaluation formula is dimensionless and that the different aspects of the path (e.g., length versus curvature) are balanced appropriately. This step is crucial when combining multiple metrics into a single evaluation score, as it prevents any one metric from disproportionately influencing the final result.

- The evaluation should **prioritize paths that minimize length and curvature**. In most path planning scenarios, especially for vehicles or robots, the goal is to find the most efficient path from point A to point B. Efficiency can be measured in terms of:
 - Path Length: Shorter paths are generally preferred because they reduce the distance the vehicle or robot needs to travel, therefore saving energy and time.
 - Curvature: Paths with less curvature are preferred because sharp turns can be difficult for vehicles to navigate, especially at higher speeds. Minimizing curvature reduces the risk of instability of the vehicle.

The combination of these requirements leads to a path evaluation formula that is both practical and effective.

To implement this path evaluation effectively, it was essential to accurately measure the path's length and curvature change, as these are critical components of the evaluation formula.

The path length was calculated by summing the distances between consecutive points along the spline, ensuring that even small variations in the path's trajectory were captured as given by equation 3.27.

$$L = \sum_{i=\min \text{ par}}^{\max \text{ par}} s(i) \quad (3.27)$$

where $s(i)$ denotes the length of the i -th curve segment of the spline measured between two points of the spline using Euclidean distance.

The curvature change of a spline path is quantified by evaluating how the curvature of the path varies along its Length. The curvature change (CC) calculated by:

$$CC = \int_{\min \text{ par}}^{\max \text{ par}} \frac{dk}{ds} \quad (3.28)$$

represents the total variation in curvature along the path, where $\frac{dk}{ds}$ measures how curvature itself changes as a function of arc length, and integrating the curvature derivative over the path length

derivative provides a comprehensive metric of curvature variation.

As this equation involves an integral, it has to be approximated in order to compute it in a programming environment. The approximation is conducted through a discretization of the path into a series of small segments. For each segment, the curvature change and segment length are approximated using Finite Difference Approximation. Let $\Delta s(i)$ denote the length of the i -th segment and $\Delta k(i)$ the change in curvature over this segment. Then, the trapezoidal rule is used to approximate the integral. This is achieved by summing up the ratio of curvature change to segment length over all segments as given by equation 3.29:

$$CC = \sum_{i=\min_par+step}^{\max_par} \frac{\Delta k(i)}{\Delta s(i)} \quad (3.29)$$

If $k(i)$ is the curvature at the i -th segment, then $\Delta k(i)$ can be expressed as:

$$\Delta k(i) = |k(i) - k(i - 1)| \quad (3.30)$$

where $k(i - 1)$ is the curvature of the previous segment. The absolute value is used to prevent cancellation of terms: curvature can be negative or positive according to the convexity or concavity of the curve. When summed together, a neutralization could happen resulting in an insignificant value. This could be solved by introducing the squared difference between $k(i)$ and $k(i-1)$. However, it will minimize the result to a negligible value for the overall analysis as the curvature values are around the magnitude of 10^{-2} or less.

The summation provides a cumulative measure of curvature changes relative to the segment lengths along the entire path, offering insight into the overall curvature dynamics of the spline. The formula for cc evaluates the total effect of curvature changes normalized by segment lengths over the path. This metric is useful for understanding how the path's curvature varies and helps in optimizing paths to ensure smooth and efficient navigation.

To develop a cost function that integrates both path length and curvature, we explore two distinct approaches: Exponential Weighted Path Evaluation and Normalized Weighted Path Evaluation. These approaches use weights to prioritize the significance of each component in the evaluation process.

3.3.2.1 First approach: Exponential Weighted Path Evaluation

The Exponential Path Evaluation is based on A. Elshamli, et al. method [17]. As explained in section 2.3, they consider path length, smoothness and clearance combined in a weighted cost function. Their approach of measuring path length and smoothness is considered here with some changes to fit it into the use case.

Path length term is measured in [17] as follows:

$$L = \sum_{i=1}^{n-1} d(s_i) \quad (3.31)$$

Whereas, Path smoothness is measured as follows:

$$S = \sum_{i=2}^{n-1} \exp(a(\theta_i - \alpha)) \quad (3.32)$$

where θ_i represent the steering angle at the i -th segment, and α denote the desired steering angle.

In addition to path clearance, the values are weighted and summed. However, this summation is not normalized, as it combines a distance term (which has physical units) with smoothness and clearance terms derived from exponential functions. In this approach, the exponential function is employed to normalize both the distance and curvature change terms. Normalization is needed in the evaluation function to ensure that different terms with varying units and scales contribute proportionally to the overall score. It balances the influence of each term, such as distance and smoothness, making the evaluation fair and consistent across different dimensions. Without normalization, terms with larger magnitudes or units could disproportionately affect the outcome.

The cost function of the weighted terms is given by equation 3.33:

$$CF_{\text{exponential}} = \omega_c \cdot \underbrace{e^{\alpha \cdot (\text{current}_{cc} - \text{ref}_{cc})}}_A + \omega_L \cdot \underbrace{e^{\beta \cdot (\text{current}_L - \text{ref}_L)}}_B \quad (3.33)$$

where

- ω_c and ω_L are the weights assigned to the curvature change term and the length term, respectively. These weights determine the relative importance of curvature change and path length in the overall evaluation.
- A is the Curvature Change term of the cost function

- B is the Length term of the cost function

The length term is given by:

$$A = e^{\beta \cdot (\text{current}_L - \text{ref}_L)} \quad (3.34)$$

The curvature change term is given by:

$$B = e^{\alpha \cdot (\text{current}_{cc} - \text{ref}_{cc})} \quad (3.35)$$

where:

- *current* refers to the path being evaluated
- *ref* refers to the reference path.
- α and β are factors that rationalize the exponential terms because the length is in the range of thousands of millimeters while the curvature is around the magnitude of 10^{-3} . Without these factors, the two terms would differ significantly, leading to incorrect analysis of the impact of each term.

Using the cost function from equation 3.33, the minimization problem is deduced:

$$Z_{\text{exponential}}^* = \arg \min (\omega_c \cdot e^{\alpha \cdot (\text{current}_{cc} - \text{ref}_{cc})} + \omega_L \cdot e^{\beta \cdot (\text{current}_L - \text{ref}_L)}) \quad (3.36)$$

with constraints:

$$K_i < K_{\max} \quad \text{for all } i = 1, \dots, N_{\text{segements}}$$

and

$$\text{CollisionCheck}(\mathbf{point}_j) = 0 \quad \text{for all } j = 1, \dots, N_{\text{ScanPoints}}$$

where

- ω_c and ω_L are the weights assigned to the curvature change term and the length term, respectively. These weights determine the relative importance of curvature change and path length in the overall evaluation.
- K_i the curvature at the i^{th} path segment.
- K_{\max} the maximum tolerated curvature
- \mathbf{point}_j represent the j^{th} scan point in space.
- $\text{CollisionCheck}(\mathbf{point}_j)$ be a boolean function that returns 1 if the point \mathbf{point}_j collides with the robot and 0 otherwise.

3.3.2.2 Second approach: Normalized Weighted Path Evaluation

The Normalized Weighted Path Evaluation is based on the division of the path's Length and Curvature Change measured respectively using the equations ?? and 3.29 respectively by the reference path's Length and Curvature Change.

The normalized cost function is given by equation 3.37:

$$CF_{Normalized} = \omega_C \cdot \underbrace{\frac{\sum_{i=j \text{ min par}}^{\text{max par}} \frac{\Delta k(i)_j}{\Delta s(i)_j}}{\sum_{i=ref \text{ min par}}^{\text{ref max par}} \frac{\Delta k(i)_{ref}}{\Delta s(i)_{ref}}}}_C + \omega_L \cdot \underbrace{\frac{\sum_{i=\min \text{ par}}^{\text{max par}} s(i)_j}{\sum_{i=\min \text{ par}}^{\text{max par}} s(i)_{ref}}}_D \quad (3.37)$$

Where: - ω_c and ω_L are the weights assigned to the curvature change term and the length term, respectively. These weights determine the relative importance of curvature change and path length in the overall evaluation.

- C is the Curvature Change Term
- D is the Length Term

The curvature change term is given by:

$$C = \frac{\sum_{i=j \text{ min par}}^{\text{max par}} \frac{\Delta k(i)_j}{\Delta s(i)_j}}{\sum_{i=ref \text{ min par}}^{\text{ref max par}} \frac{\Delta k(i)_{ref}}{\Delta s(i)_{ref}}} \quad (3.38)$$

where j denotes the current path being evaluated.

The length term is given by:

$$D = \frac{\sum_{i=\min \text{ par}}^{\text{max par}} s(i)_j}{\sum_{i=\min \text{ par}}^{\text{max par}} s(i)_{ref}} \quad (3.39)$$

Using the cost function 3.37, the minimization problem is deduced :

$$Z_{Normalized}^* = \arg \min \left(\omega_C \cdot \frac{\sum_{i=j \text{ min par}}^{\text{max par}} \frac{\Delta k(i)_j}{\Delta s(i)_j}}{\sum_{i=ref \text{ min par}}^{\text{ref max par}} \frac{\Delta k(i)_{ref}}{\Delta s(i)_{ref}}} + \omega_L \cdot \frac{\sum_{i=\min \text{ par}}^{\text{max par}} s(i)_j}{\sum_{i=\min \text{ par}}^{\text{max par}} s(i)_{ref}} \right) \quad (3.40)$$

with constraints:

$$K_i < K_{\max} \quad \text{for all } i = 1, \dots, N_{segements}$$

and

$$\text{CollisionCheck}(\mathbf{point}_j) = 0 \quad \text{for all } j = 1, \dots, N_{ScanPoints}$$

Where

- ω_c and ω_L are the weights assigned to the curvature change term and the length term, respectively. These weights determine the relative importance of curvature change and path length in the overall evaluation.
- K_i the curvature at the i^{th} path segment.
- K_{\max} the maximum tolerated curvature
- point_j represent the j^{th} scan point in space.
- CollisionCheck(point_j) be a boolean function that returns 1 if the point point_j collides with the robot and 0 otherwise.

The algorithm that measures the path quality is detailed through Pseudo Code 3.

3.4 Path Optimization

After successfully developing the tools to partition the stations, create spline-based pattern paths, and evaluate their quality in line with the trucks' properties and target outcomes, the paths are ready for the optimization phase. **The input of this section is a range of paths along with their evaluation scores and the output is the optimal path to be driven.**

The utility of the path optimization process lies in its ability to identify the most efficient and effective path for the vehicle to follow, based on various criteria. By considering key factors such as path length, curvature, and smoothness, the optimization algorithm ensures that the selected path not only adheres to the vehicle's operational constraints but also minimizes risks associated with challenging maneuvers. This process plays a crucial role in improving overall system performance, as it helps reduce fuel consumption, wear on vehicle components, and driving complexity. Additionally, the optimized path leads to better time efficiency and safer operations, particularly in complex environments where tight turns or narrow spaces can hinder navigation.

3.4.1 Implementation

As discussed in section 3.1, The meta-heuristic approach is used to optimize the spline-based pattern paths. Based on the Literature review the choice was made around testing 5 meta-heuristic optimization algorithms then assessing each algorithm's performance. The algorithms are: Particle Swarm Optimization (PSO), Differential Evolution (DE), Genetic Algorithms (GA), Simulated Annealing (SA), and Ant Colony Optimization (ACO). Those algorithms were selected due to their capabilities of solving the local optima problematic and their applications in robotics path planning although considered recent for some of the algorithms.

The optimization process is detailed through Algorithm 4. After initializing the optimization problem-related parameters, The algorithm starts the evolution of the generations or the iterations. In each iteration it generates a fixed number of individuals. **The decision vector of each individual is the transition point. The optimization algorithm starts by placing random transition points inside the subpolygons.** First the initial individuals are generated. For Population based algorithms like GA and DE, generate an initial population of candidate points (x, y) , for swarm-based algorithms like ACO and PSO, initialize particles or ants randomly, For Simulated Annealing (SA), start with a single solution point (x, y) .

Each transition point is used to generate a path as explained in section 3.3.2 then evaluated through the method in section 3.3.3. The evaluation result is the fitness of the path that the optimization algorithm bases its results on. By now the initial generation is completed. Then, the algorithm iterates

until the maximum number of iterations is met. The reason behind choosing a maximum number of iterations is that the fitness function is not tangible. It can vary according to many factors like station configuration and dimensions and navigation environments. Tuning a goal fitness that fits all cases can be limiting if it set higher than the possible optimal fitness and causes sinking in suboptimal solutions or can constrain the optimizer if set too low: the optimizer can quit without solutions. Then the algorithm proceeds to generate new points following the meta-heuristic algorithm:

- GA: Apply selection, crossover, and mutation to generate new points (x, y) .
- DE: Create new trial points by combining the difference between vectors of points.
- PSO: Update positions of particles based on their velocities, influenced by the personal and global best.
- SA: Randomly perturb the current point (x, y) and generate a new path.
- ACO: Ants select the next points (x, y) based on pheromone trails and heuristic information.

Afterwards, it generates Corresponding Paths, evaluates Fitness of New Paths and updates the Population or Solution Set in relevance to the meta-heuristic algorithm:

- GA: Select the next generation of points based on fitness, using techniques like elitism or tournament selection.
- DE: Retain points with better fitness, replacing weaker ones.
- PSO: Update the personal best positions and global best positions of particles.
- SA: Accept or reject new points based on a probabilistic function that includes temperature.
- ACO: Update pheromone trails based on the quality of the paths found, and reduce pheromone levels globally (evaporation).

The last step of each iteration is to update the algorithm parameters:

- GA/DE/PSO: Adjust crossover rates, mutation rates, or particle velocities.
- SA: Reduce temperature according to the cooling schedule to reduce acceptance of worse solutions over time.
- ACO: Evaporate pheromone globally and reinforce the best paths with additional pheromone.

Once the stopping criteria is met, the algorithm returns the best path that it found.

This Algorithm is ran once for each of the subpolygons. The optimization happens for both subpolygons, each optimizer returns an optimal path that uses the corresponding subpolygon. Then, the results from both optimizers are compared and the fittest is considered as the overall fittest path.

For the application of these algorithms, Pagmo library was used. Pagmo is an open-source scientific library designed for C++ that specializes in optimizing massively parallel problems. It was developed between the Max Planck Institute for Astronomy and the Advanced Concepts Team, at the European Space Research and Technology Center [45]. Pagmo provides an exhaustive toolset of meta-heuristic optimization techniques including the original Algorithms and the improved versions.

3.4.1.1 Obstacle Avoidance in the Pattern Based Approach

This approach is designed for complex, dynamic environments characterized by an abundance of obstacles, such as Operators, Pallets, Materials, Shelves, and other vehicles, both inside and outside the station perimeter. To navigate these environments, an obstacle avoidance feature is essential. The obstacle avoidance mechanism, integrated into the Pattern-Based Solution, is managed by the Optimizer, which assigns high penalties (referred to as "Knockout" values) to paths that collide with or come too close to obstacles (Fitness values \ll Knockout). This approach, as detailed in Algorithm 3, effectively eliminates colliding paths by making them unfavorable during optimization. For instance, as shown in Figure 3.16, when obstacles block one of the subpolygons of the station, the Optimizer selects an alternate subpolygon. However, this method has limitations—if both subpolygons are blocked, the pattern cannot navigate around the obstacles. To address this, two additional waypoints are introduced: one between the robot and the transition point, and the other between the transition point and the destination. These waypoints increase flexibility by allowing the path to deviate from nearby obstacles. Their positions are optimized along with the transition points, as illustrated in Figure 3.17, ensuring that each path candidate is created and evaluated using the same Evaluation approach.

Algorithm 4: Generic Optimization Algorithm with Path Evaluation

Input: Problem parameters, Population size, Max iterations, Algorithm-specific parameters
Output: GeneratedOptimalPath

1 Initialize population size, max iterations, algorithm-specific parameters;
2 **Initialize Population of Points**
3 Generate an initial population of candidate points (x, y) .
4 **Evaluate Fitness for Initial Paths**
5 CreateEvaluationPath(x, y);
6 MeasureNormalizedMetric(path); **Repeat until Termination Condition Met (max iterations):**

7 **begin**

8 Generate New Points
9 Generate Corresponding Paths
10 Evaluate Fitness of New Paths
11 Update Population or Solution Set
12 **Algorithm-Specific Update Step**

13 **Return Best Point and its Path:**
14 Return the best point (x, y) and its corresponding path found during the search process.

Conclusion

This chapter focused on the development and implementation of the optimized local path planning approach. The geometric partitioning of the station allows the robot to identify zones where path transitions can be made. Paths were generated using spline theory and evaluated with a cost function based on path length and curvature change. Path optimization was subsequently applied to minimize the cost function value, ensuring effective navigation within the warehouse. With the development phase complete, the next step is to test and validate the proposed solution in practical scenarios.

Chapter 4

Test and Validation of the Proposed Solution

Chapter 4

Test and Validation of the Proposed Solution

Introduction

This chapter presents the results of testing and validating our proposed path planning and optimization algorithms. We conducted experiments under various conditions, evaluating factors such as path quality, algorithm performance, and robot execution. By comparing our approach to OMPL and analyzing the results, we aim to demonstrate the effectiveness of our solution for real-world AMR applications. For this section 3 test environments are used:

- Independant Simulation Environment: This environment is created outside the RACK environment to validate the chosen approaches before implementing the developed features on the real system. It recreates the Station and the Shelf without sensor inputs or kinematic constraints. To simplify the test, the robot is modeled by a point instead of its proportional chassis size.
- RACK simulation environment: It is the simulation environment used in the team to simulate the outcomes of the developed features in the same conditions as the real test. It includes all the sensor input and makes it available for the test: Localization, Obstacle Detection, and Object Recognition features. It can be Offline or Online
 - Offline Testing: is the re-creation of the warehouse and the test environment in a complete model as seen on figure 3.7. A simulated robot is available to place at a starting point, to navigate the planned paths as well as to perceive its surroundings and use the sensor input for its processing. Objects like simulated obstacles can be added.
 - Online Testing: is a projection of the test on the AMR to the Simulation environment.

The simulation visualizes the output of the sensors like scan points and makes a debugging tool available for interpretation of results, debugging, and optimization.

- AMR Field Tests: the AMR is commissioned with the test algorithms, validated through the RACK simulation environment tests. The truck navigates the planned paths in the real warehouse and deals with real stations, shelves, pallets, obstacles and general surrounding objects.

1 | Path Creation Test Results and Validation

The implemented Path Creation Approach explained in section 3.2.3 was first tested in a simulation environment composed of one Station. This environment emulates the RACK model of the test warehouse and was used to test and validate the approach before testing it inside the RACK simulation first and then on the AMR.

For this environment, the implementation results of the subpolygons from section 3.1 were used for the path creation. The created subpolygons are used as transition zones. As a first test of pure path creation, the transition points are previously fixed at the center of the subpolygons. The path is created by placing the robot in the simulation in a starting position and testing different target locations.

The obtained results are of smooth splines adhering to the pattern and linking the truck to the destination pallet while passing by a transition location. The independant Simulation Environment tests show the pattern spline-based path as given by figure 4.1: The path start at the truck's position, transitions in one of the transition subpolygons to change driving direction and joins the target. The resulting path on the RACK simulation environment which is the real testing environment show as well the creation and plotting of the pattern path on the simulated station as given by 4.2 and 4.3.

This approach is validated and is ready as a basis for the next test steps. The validation is for the following reasons:

- The path creation module integrates the subpoygon functionality successfully: the use of a transition point from the subpolygons is effective when tested with a complete path.
- The created paths satisfy the intended pattern: they link the truck to the transition point, then, the latter to the target. Inside the RACK simulation environment, it was verified that the direction change occurs: the AMR switches from a negative speed at the first section when

driving in opposite direction the first part of the spline path until the transition point, to a positive speed when driving in main driving direction the second part of the spline path from the transition point to the target.

- The paths link the start to the chosen target accurately which reflects the validation of the transformations implemented at the development section of the Path Creation.

2 | Path Evaluation Test Results and Validation

In order to discriminate the Path Evaluation methods, both approaches (3.3.2.1 and 3.3.2.2) were tested in the Independant Simulation Environment. Tests were ran on 10 different spline paths that were generated with transition points scattered in the station 4.4. Different locations of transition points were used to stress the metric outcomes by creating good and bad paths. The Exponential Weighted Path Evaluation was tested with $\alpha = 2$, $\beta = 0.0007$, $\omega_c = 0.7$ and $\omega_L = 0.3$. The results are shown in figure 4.5: The bar chart reflects the Evaluation score of each spline path from figure 4.4. Each bar color reflects the same color spline. The Normalized Weighted Path Evaluation was ran for two tests on the same splines set with:

- $\omega_c = 0.7$ and $\omega_L = 0.3$
- $\omega_c = 0.5$ and $\omega_L = 0.5$.

The results are shown in figures 4.6 and 4.7

For the Exponential Weighted Path Evaluation, the results are correct. It is easy to differentiate poor-quality paths. For example, the Blue spline was used as the reference path, while the Orange, Gray, and Purple paths were intentionally created as bad paths. The Orange and Gray paths generate significant curvature near the destination, making it challenging for the vehicle to navigate and arrive in the correct position and orientation given the narrow aisle that it has to turn and navigate in as shown by figure 4.8. Given the high curvature and the proximity to the destination, the truck

decelerates and moves very slowly. Changes that it stops at the correct orientation that allows it to pickup the pallet are very low. Such path have to be avoided at all costs. The Purple path is longer and curved at the starting area. Furthermore, the Brown path demonstrates the best overall fitness. Although it is short, it introduces high curvatures at the transition and destination areas. Compared to the Blue and Red paths, the Brown path is shorter but less smooth. The Exponential Evaluation also favors the Dark Green path to the Pink one, even though the concentrated curvature at the end of the green path is high. In conclusion, this evaluation method is very sensitive to path length and less sensitive to high concentrated curvatures. This is due to the high factor of the length term, in the range of thousands of millimeters, and the low factor of the curvature term which is around the magnitude of 10^{-3} . It is inconvenient to change the factors ω_c and ω_L by increasing ω_c and decreasing ω_L as the difference becomes huge while it is mandatory to attribute importance to both factors. Besides, this Metric is very sensitive to the change of the α and β factors. These factors must be carefully tuned to fit all use cases and account for varying station sizes and configurations. However, finding factors that are scalable across different use cases is not straightforward.

On the other hand, The Normalized Weighted Path Evaluation, chose the Red path as the best fitness, outperforming the Blue pattern path. This is due to the remarkable less curvature of the Red path at the start and transition locations due to its proximity to the transition polygon and distance to the destination. These factors allow for smooth driving along the path. Comparing figures 4.6 and 4.7, the approach of outweighing the curvature over the length outperforms the equal weights approach. The Pink path is visibly better than the Brown due to better smoothness and the first weights approach discriminates them better. Given the challenges associated with driving along smooth paths, it is a strategic decision to prioritize the curvature term over the length term. Navigating a slightly longer path is far less difficult than handling a path with sharp curves. This approach is not affected by the difference of range between length and curvature metrics given that they are each divided respectively by the reference path's length and curvature. This not only balances out the two terms but also makes it fit all use cases and account for varying station sizes and configurations given that the reference path is always relevant to the present station.

As a final point, **the selected approach is the Normalized Weighted Path Evaluation** with $\omega_c = 0.7$ and $\omega_L = 0.3$ given by equation 3.37.

The Path Evaluation Approach is validated and can be used for the path Optimization phase. The approach was validated for the following reasons:

- The Selected Evaluation method satisfies the goal of optimizing path length and thus travel time and limiting high curvature and challenging turns of the bulky truck by optimizing curvature change.

- Using the Evaluation Method, good and poor quality pattern paths can be discriminated by affecting a score to each path according to its properties and comparing them.

The approach is ready to be used as the cost function of the optimizer.

3 | Path Optimization Test Results and Validation

Using the Path Creation and the Selected Evaluation approach, the optimization approach is tested. First the Optimizer is tested in an empty station, then it is tested against obstacles placed inside the station in different locations. The optimization algorithm is ran first on The Independant Simulation Environment to verify the relevance of the optimization approach to the pattern-based path. For this test, The Optimizer evaluates 10 generations of 10 paths for each subpolygon, it calculates the fitness value for each path and saves the overall best fitness value from both subpolygons. Figure 4.9 shows the result inside the Independant Simulation Environment for a station empty of obstacles: The figure illustrates the candidate paths of the first of the 10 generations, along with the optimum paths from both subpolygons in bold Red and Brown "champion paths" as called in the algorithm. The algorithm successfully rejects poor quality paths like the lowest right red path which has two direction changes along the path due to the sharp turn in the beginning, and the highest left blue path that has an unfeasible sharp turn at the target. The approach is validated at this stage.

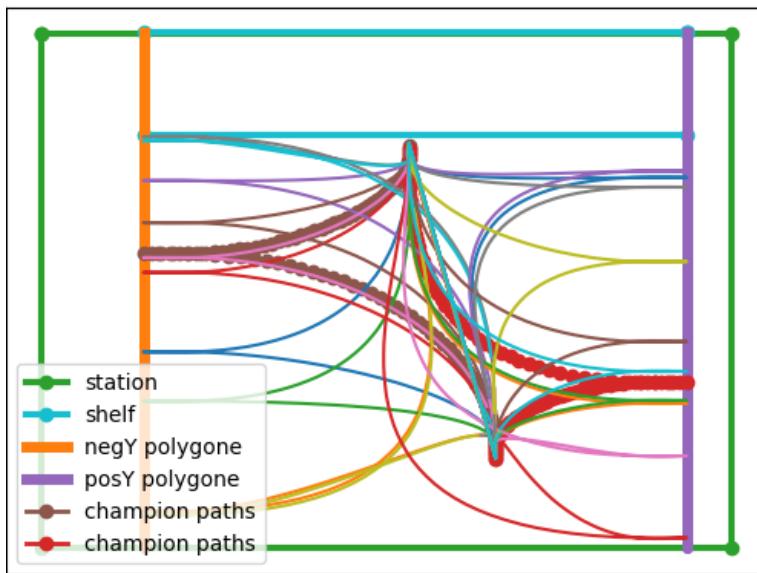

Figure 4.9: Optimizer results in empty station of one of 10 generations with the overall best paths visualized in bold red and brown

The second test is ran with obstacles placed in different positions in the station. The Algorithm results on figure 4.10 illustrate that the optimizer is capable of generating paths the avoid obstacles. The optimizer does generate paths that cross the quadrilateral obstacle but those paths are eliminated by better quality paths: the optimum paths in Brown. The quadrilateral obstacle was placed in a critical area, the center of the station to stress the optimizer. On the other hand, the rectangle obstacle was placed in the right corner of the station at a far distance from the start position, the optimal transition area inside the subpolygon, and the target. Although the two paths are correct, the brown path is highly curved at the beginning because it avoids the quadrilateral obstacle. However, the red path is smoother at the start and destination segments of the path.

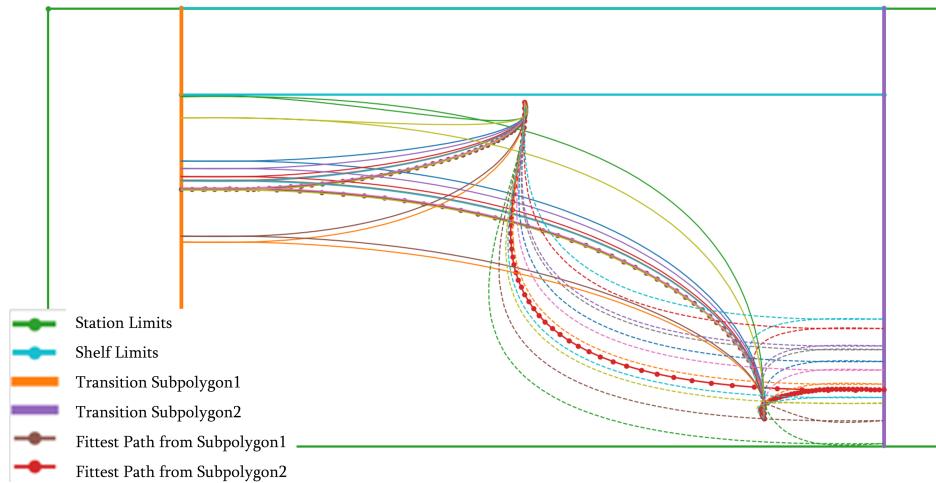

Figure 4.10: Optimizer results in presence of obstacles of one of 10 generations with the overall best paths visualized in bold red and brown

Another obstacle situation was tested and illustrated by figure 4.11. The obstacles in this situation were placed in the center of the station . For this case the regular optimizer was unable to find a solution that does not collide with the obstacles. However, by increasing the number of the waypoints (approach in section 3.4.2.1), The optimizer was effective in finding collision free paths.

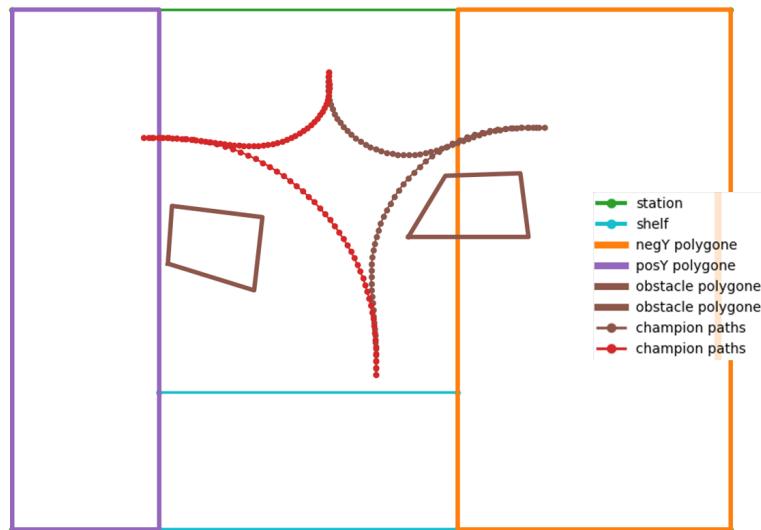

Figure 4.11: Optimizer results in presence of obstacles and influence of increasing path waypoints

The approach is validated for a moderate complexity environment.

Given that the approach was validated in the Independant Simulation Environment, the tests are

ran on the RACK Simulation Environment. Two test scenarios are created: The first is called the *Simple Environment* which is an obstacle-free station and the second is called the *Complex Environment* where an obstacle is placed in one side of the station. In reality, the *Simple Environment* is not simple because the sensors detect the warehouse walls, shelves, objects, and other vehicles but the station area is free of stranger objects. The test in the *Simple Environment* illustrated by figure 4.12 was done by placing the AMR in the simulation in the starting position (green rectangle) and selecting the target position on the simulation model. The expected target position is the red rectangle. The path is planned following the pattern and links the AMR from its start position to the target position. The blue prints along the path represents the positions that the AMR will be at when driving the path. The footprint helps to ensure that the AMR will not collide with surrounding objects and validate the optimizer's ability to avoid obstacles.

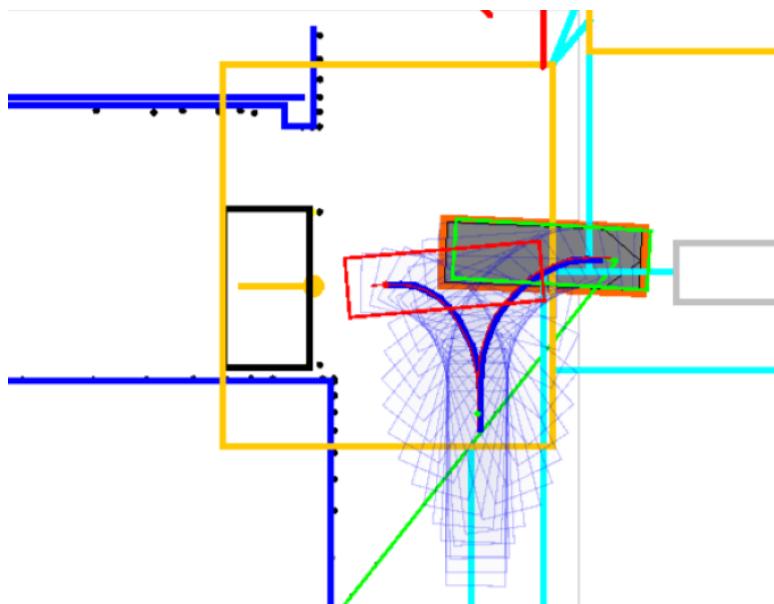

Figure 4.12: Optimizer results in a simple environment tested inside the RACK simulation: Start Position

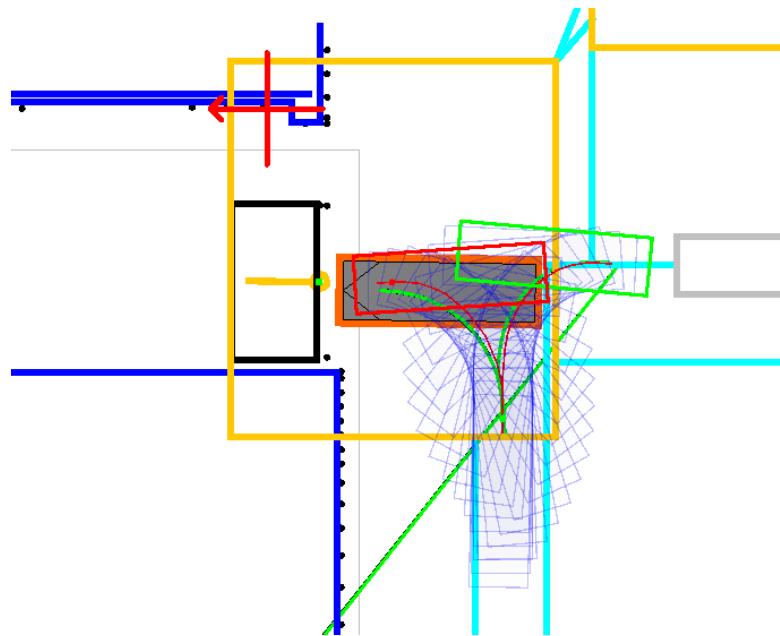

Figure 4.13: Optimizer results in a simple environment tested inside the RACK simulation: Target Position

As for the *Complex Environment*, an obstacle was placed at the side of the station blocking one of the subpolygons as illustrated in figure 4.14: the blue rectangle at the bottom of the figure. The planned pattern path (red path) transitions in the opposite subpolygon as it is clear of obstacles. The optimizer successfully generates a pattern path that avoids known obstacles such as the shelf and the warehouse walls as well as new obstacles like the blue rectangle. The generated path is aligned with the kinematic constraints of the vehicle as illustrated on figure 4.15: it avoids highly curved turns and limits the direction changes to one thus ensuring a smooth navigation. Finally, the truck docks the target location at the desired position as shown in figure 4.16: The forks are facing the shelf and ready to start pick up/ drop process.

Remark: the shift of the final position of the vehicle on figure 4.16 is due to control issues. Currently the path following is not completely correct and requires control improvement.

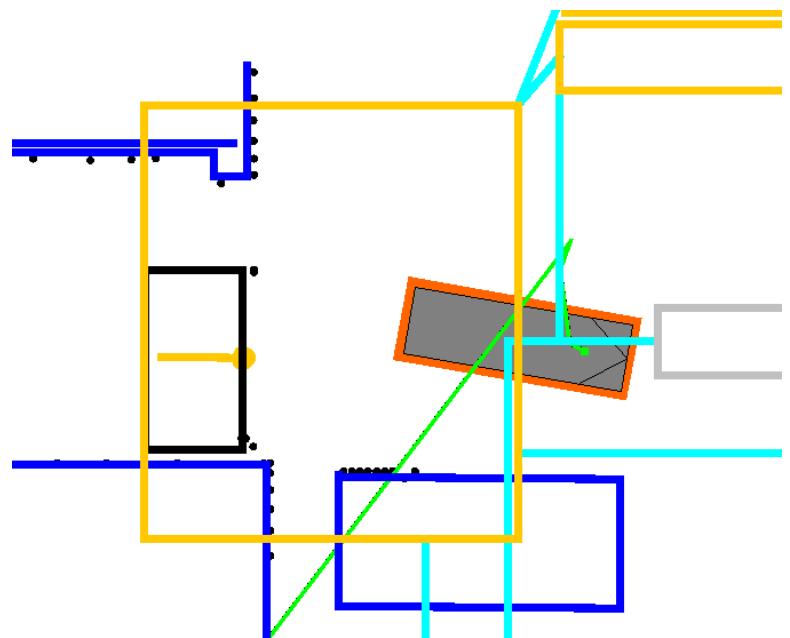

Figure 4.14: Optimizer results in a Complex environment tested inside the RACK simulation: Start Position

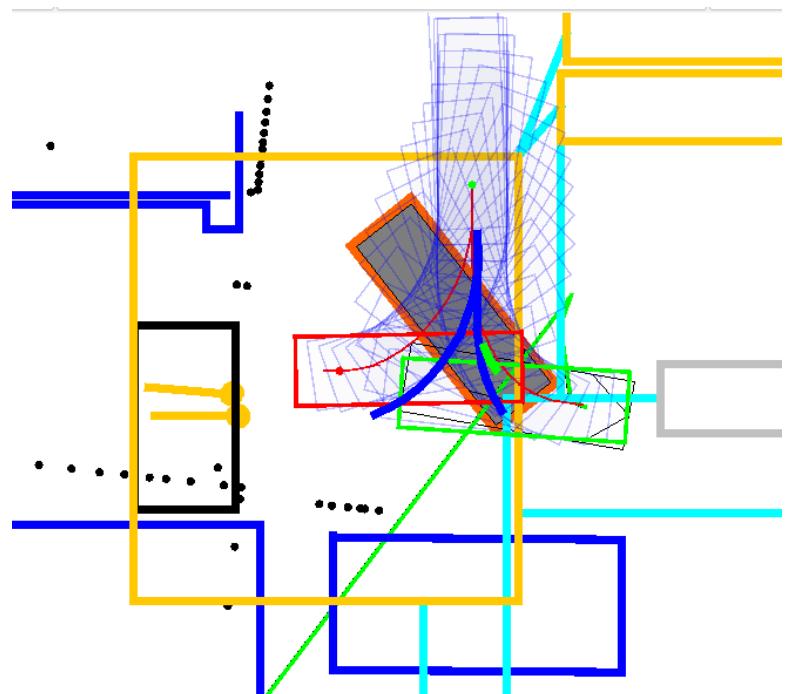

Figure 4.15: Optimizer results in a Complex environment tested inside the RACK simulation: AMR Navigating the path

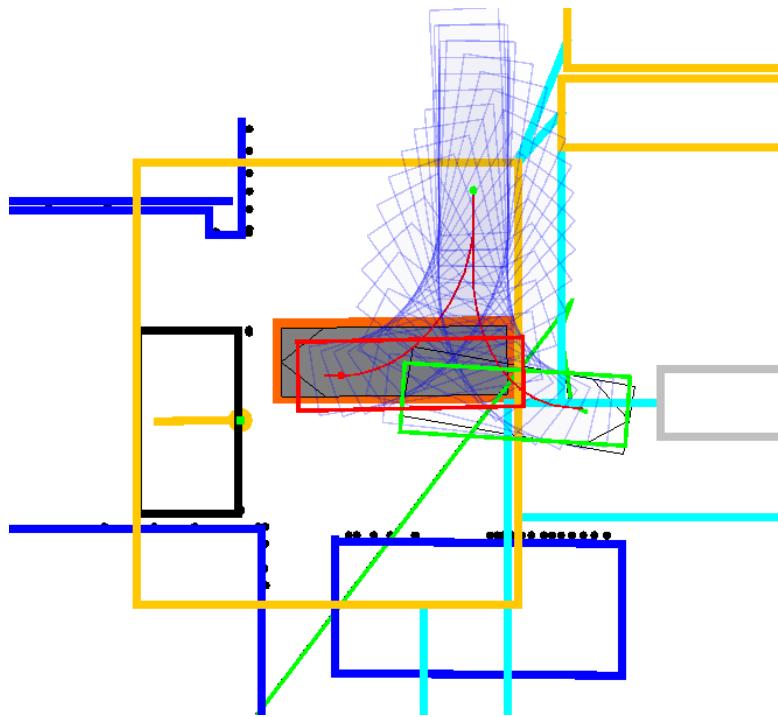

Figure 4.16: Optimizer results in a Complex environment tested inside the RACK simulation: Target Position

Using the *Simple Environment* and the *Complex Environment* tests were ran inside the RACK Simulation Environment to compare the performance of the Metaheuristic Algorithms: GA, DE, PSO, ACO, and SA.

The same starting and Target Positions were used for each scenario. For the *Complex Environment*, the same obstacle was used for all the algorithm tests to create the same test conditions, the obstacle used is marked in green on figure 4.17. All algorithms were configured to evolve around 200 candidates. The comparison between the Algorithms in the simulation is based on:

- The Planning Time: the time that each algorithm takes to evolve a solution.
- The Created Path's Fitness Values.

Table 4.1 shows the planning times for simple and complex Environment for each algorithm. For the Simple Environment, the DE algorithm prevails at a planning time of $27ms$. The worst planning time is with the SA algorithm at $80ms$. GA, PSO, and ACO have the same range of Planning time 56 to $59ms$. For the complex Environment, The ranking is the same: the best algorithm in terms of planning time is the DE at $44ms$, next comes the ACO at $65ms$. The least performing algorithm remains the SA with a planning time of $78ms$. It is noticeable that the planning time

increased overall for almost all the algorithms in the complex environment scenario. This is due to the checking of the scan points that increase as more objects are introduced around the AMR.

Using the planning time based comparison the DE algorithm is the most performing in terms of planning time.

Table 4.2 details the fitness values for both scenarios. It is worth mentioning that the obstacle is placed inside subpolygon1 in this case. For the Simple Environment, the GA was able to find the fittest candidate at an evaluation score of 0.32 in subpolygon2, however, the DE has the highest fitness values 0.652 in subpolygon1 and 0.56 in subpolygon2 even though it was the fastest in terms of planning time. For the complex Environment, the PSO was the fittest with an evaluation score of 0.38 in subpolygon2 and very close was the DE with 0.384. As for subpolygon1 where the obstacle stands, the fitness values are very high. The values can be clustered into two groups:

- Knockout value: this is the cluster of the fitness values equal to 50. It was obtained with the ACO and DE. The knockout value is the fitness value assigned to the paths that collide with obstacles. Returning a fitness function of 50 means that the optimizer was not able to find a path at that subpolygon.
- High values < 50: For GA, PSO, and SA the fitness values are respectively 31, 1.159, and 1.258. These values are caused by penalizing the high curvatures. If a path's maximum curvature exceeds the maximum tolerated curvature of the truck, the Path gets penalized by emphasizing its curvature. Despite the poor quality of the paths, these algorithms still found feasible solutions to get around the obstacle.

Using this comparison, the PSO algorithm outperforms the other algorithms in complex environments as it finds the fittest path which refers to the shortest path and the least curvature change and also finds a path in the constrained subpolygon where the obstacle stands.

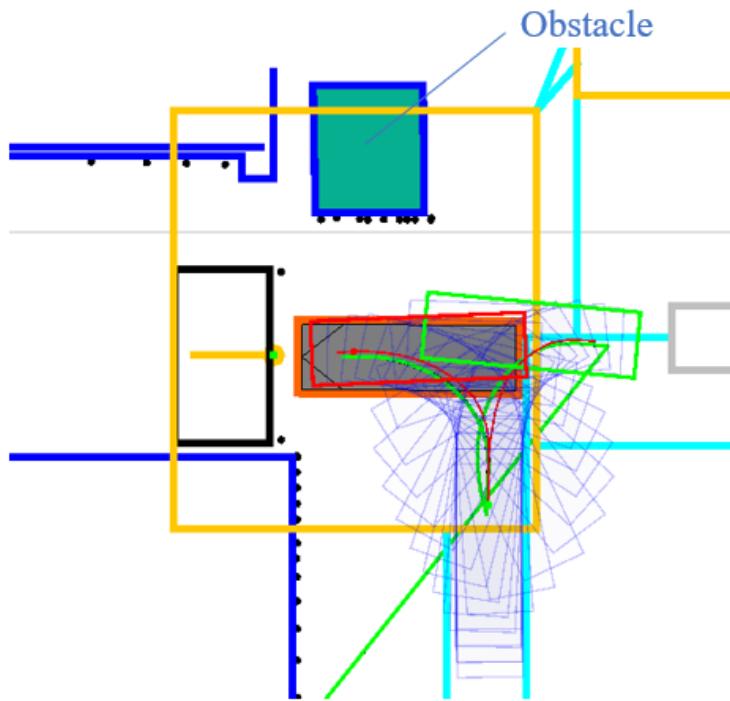

Figure 4.17: Obstacle Used for Metaheuristic Algorithms comparison in the complex scenario

Algorithm	Planning Time (Simple Environment) (ms)	Planning Time (Complex Environment) (ms)
Genetic Algorithm	57	73
Particle Swarm Optimization	59	67
Ant Colony Optimization	56	65
Simulated Annealing	80	78
Differential Evolution	27	44

4 | Field-Testing of the Solution on the AMR

This section sums up the developed module for a field test on the iGo Neo Truck. First the test Conditions are outlined, then the planning process with the sensor input are explained. Finally the planned path and navigation of the truck in each scenario are discussed.

The Approach is tested in 3 different scenarios:

- A Simple Test Environment where The station is free of obstacles.
- Moderate complexity Test Environments where obstacles are placed in 2 areas of the station: left and right sides of the shelf. The obstacles are intended to block one subpolygon.

4.1 Simple Test Environment

The truck was placed at position $x = 33026$, $y = 28070$, and $\rho = 100.0^\circ$ as illustrated by figure 4.22. The sensor input of the truck as scan points which detects the obstacles is represented by black points on the figure. Figure ?? shows the start position of the Truck inside the warehouse. The RACK simulation is now a real-time visualization of the real warehouse. The goal is to dock the shelf which is represented in the real warehouse image 4.23 by the yellow floor anchors at position $x = 33426$, $y = 22696$, and $\rho = 0.0^\circ$. They hold the reflectors that return the shelf's position. After station, shelf and target recognition, and station partitioning, the optimizer starts generating and evaluating the candidate paths. After successful processing of an optimum path, the truck start

driving it. The optimum path is illustrated on figure ?? in red. The path is followed by the truck that moves in opposite direction and negative speed until the transition location. Starting from the transition location, it drives in main direction orienting the forks towards the shelf in preparation to dock then pickup or drop.

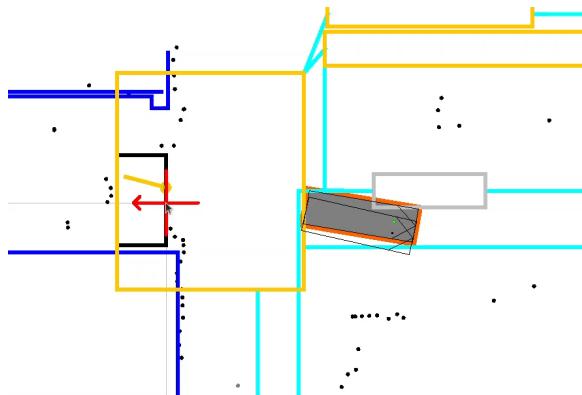

Figure 4.18: Environment and Start position of the Simple Test Scenario

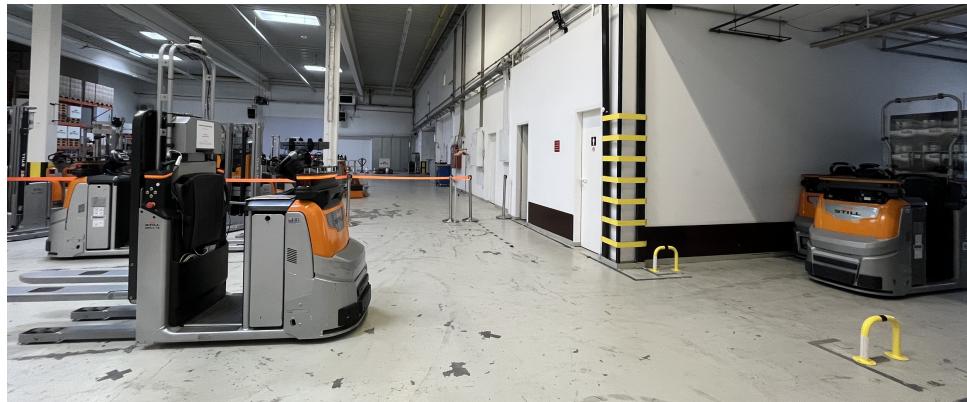

Figure 4.19: Environment and Start position of the Simple Test Scenario in a real warehouse with iGo Neo

On this picture is a real warehouse where the field test took place. The test truck is an iGo Neo and the station used is station *Emptypallets* at a global position inside the warehouse $x = 34121$, $y = 23752$, and $\rho = 0.0^\circ$. The station limits are fictitious they are not outlined in the warehouse, but they can be seen on figure 4.22. The shelf is marked by the yellow floor anchors fixed on the floor. The environment for this test is not completely simple and empty as other trucks, objects, and people are in the warehouse, yet, the station is empty.

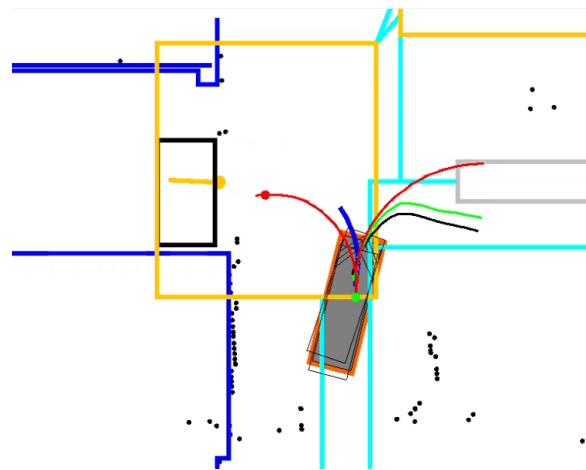

Figure 4.20: Truck in the simulation navigating the planned path: Transition phase

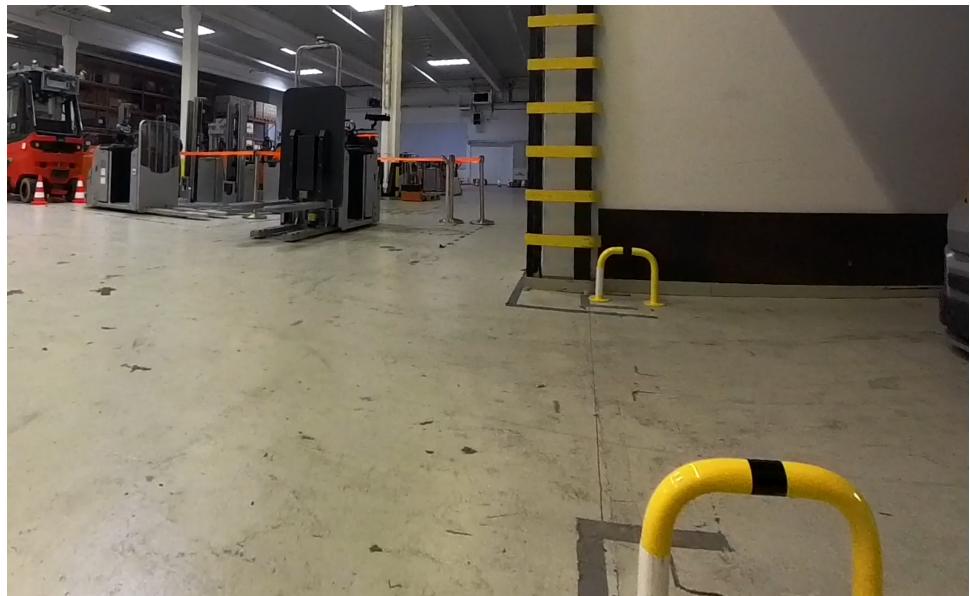

Figure 4.21: Real Truck navigating the planned path: Transition phase

The Truck follows the planned path and successfully transitions in the transition area while changing direction to orient the fork to the target.

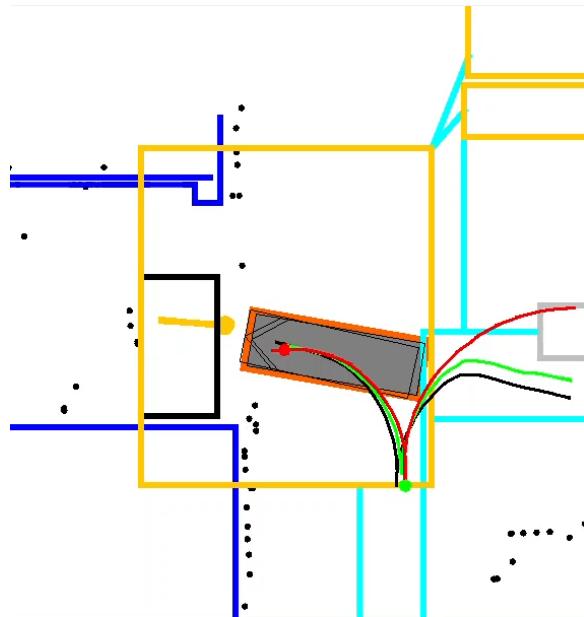

Figure 4.22: Truck in the simulation navigating the planned path: Docking phase

Figure 4.23: Real Truck navigating the planned path: Docking phase

The Truck arrives at the planned target and successfully docks the shelf with forks oriented towards it in preparation for pickup / drop.

To summarize, for the test on the AMR, the PSO Algorithm is used. The duration of Planning of the optimized path was 286ms.

4.2 Complex Test Environments

The Field-Tests in Complex Environments are conducted by placing obstacles on two sides of the station. Two test cases were carried out using two obstacle setups: Placing obstacles to the AMR's left then right as illustrate figures ?? and ???. The goal is to block one of the Transition zones, in order to test the system's flexibilty, exploration and exploitation of the transition possibilities.

4.2.1 Obstacle Setup 1: Obstacle on the left of the AMR

The truck was placed at position $x =$, $y =$, and $\rho = ^\circ$ as illustrated by figure ???. The target is set at position $x =$, $y =$, and $\rho = ^\circ$. The obstacle is as represented by figure 4.24, a two-box block set one above the other. This obstacle was scanned and represented on the RACK Simulation Environment by its corner marked by the green arrow as illustrated by figure 4.25. The black dots seen on the same figure are scan points that represent obstacles in the warehouse. Usually there is more scan points, that cover for example the visible surface of an object. For instance, the obstacle represented in figure 4.17 has scan points on its front side. In the case illustrated by figure 4.25, the scan points are reduced by using a RACK module that minimizes scan points concentrated in one area. The goal is to keep the necessary data about the surrounding objects and limit the amout of information to be processed for collision checking and path generation, thus optimizing processing time. The optimum path is planned and the optimizer generates a pattern-based trajectory that transitions inside the empty Transition Subpolygon. The generated path is illustrated in red on figure 4.27. It is followed by the truck from the start, passing by the transition area and changing directions, and docking the target at the assigned position as represented on figure 4.28.

For this test setup, the planning duration of an optimum path is of $303ms$. During this time the optimzer processed a paths that optimizes to a certain extent the path length and the curvature change proportionally to the path length.

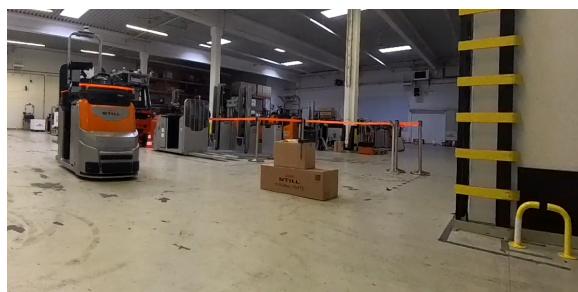

Figure 4.24: Start Position

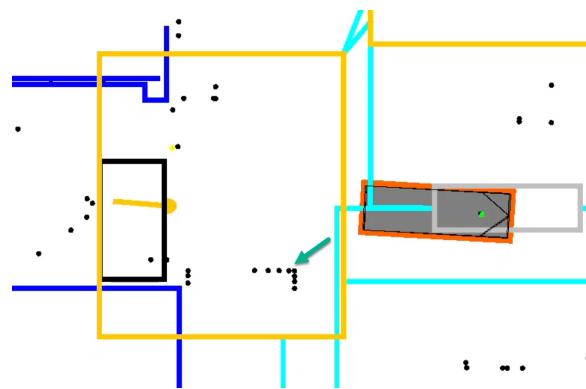

Figure 4.25: Start Position

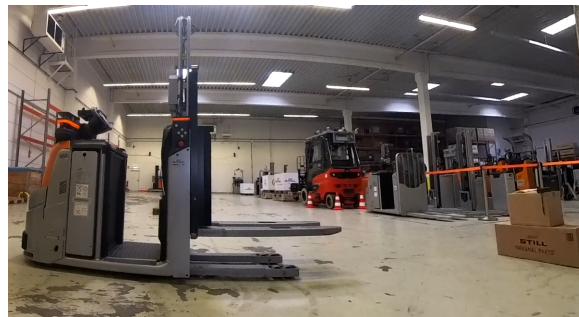

Figure 4.26: Transition Position

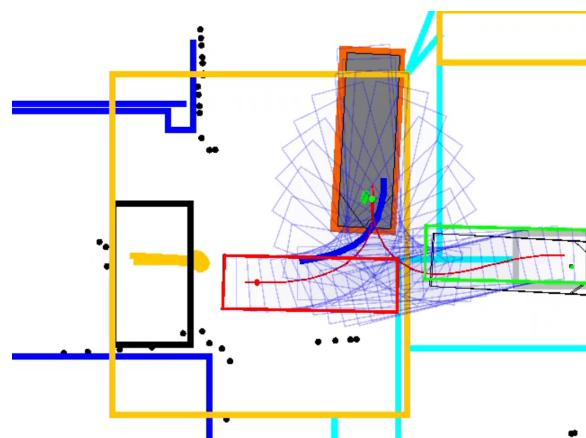

Figure 4.27: Transition Position

Figure 4.28: Target Position

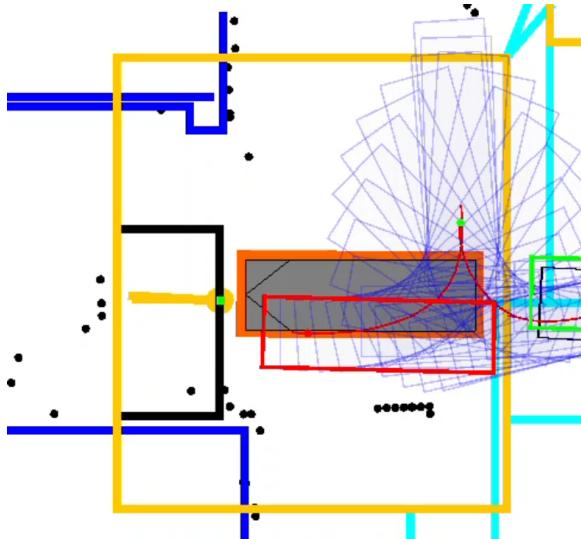

Figure 4.29: Target Position

4.2.2 Obstacle Setup 2: Obstacle on the right of the AMR

The truck was placed at position $x =$, $y =$, and $\rho = {}^\circ$ as illustrated by figure ???. The target is set at position $x =$, $y =$, and $\rho = {}^\circ$. The obstacle is a box represented by figure 4.30. This obstacle was scanned and represented on the RACK Simulation Environment by its corner marked by the green arrow as illustrated by figure 4.31. The optimum path is planned and the optimizer generates a pattern-based trajectory that transitions inside the empty Transition Subpolygon. The generated path is illustrated in red on figure 4.33. It is followed by the truck from the start, passing by the transition area and changing directions, and docking the target at the assigned position as

represented on figures 4.34 and 4.35.

For this test setup, the planning duration of an optimum path is of $295ms$. During this time the optimizer processed a paths that optimizes to a certain extent the path length and the curvature change proportionally to the path length.

4.3 Discussion of the results

The Pattern-based path planning approach was tested in 3 different scenarios. The PSO Algorithm was used for the 3 scenarios and successfully generated feasible paths for each test case. In the cases were obstacles were presented to the station the optimizer showcased the obstacle avoidance feature by rejecting colliding paths and opting for optimum candidates that scored least fitness values among the 200 generated individuals. The previous test cases and events proved that the proposed approach is a simple and feasible solution to the docking process. While the planning time in the RACK Simulation Environment was as low as $59ms$ for the Simple Environment and $67ms$ for the Complex Environment, The field-test scenarios scored planning times of $286ms$ up to $303ms$. This duration is significantly higher than the duration on the simulation. This is due to the high number of objects surrounding the vehicle which are represented by scan points that the truck needs to check for collisions for every path candidate. The traveled path can be shorter: the used Evaluation approach favors the optimization of the curvature term over the length, in other words, a longer path is better than a curved path. This minimizes the curvature but creates long paths that have room for improvement.

Conclusion

In this chapter, the proposed solution was rigorously tested and validated through a series of evaluations, beginning with path creation and extending to path optimization and real-world field

testing. The results demonstrated the effectiveness of the solution in creating, evaluating, and optimizing paths, with each stage providing valuable insights into its performance. The field tests conducted in a simple environment using an Autonomous Mobile Robot (AMR) confirmed that the proposed solution could be effectively deployed in practical scenarios. The discussion highlighted key takeaways, underscoring the robustness and applicability of the solution in real-world settings.

General conclusion

This project has explored the complex and rapidly evolving field of intralogistics, focusing on the optimization of local path planning for the autonomous forklifts' AMRs produced by STILL. The technique introduced by this thesis concerns a specific part of the global path that allows the AMR to properly dock the target. The work was structured across four key chapters, each building towards a comprehensive understanding and solution to the challenges faced in modern industrial environments.

Chapter 1 provided a thorough introduction to the host company, STILL, detailing its structure, and contributions to the intralogistics industry. By outlining the project's context, motivations, and core problematics, this chapter laid the groundwork for understanding the broader objectives and the specific goals of this thesis, particularly in optimizing path planning near pallet stations.

Chapter 2 delved into the state-of-the-art literature, offering a review of existing solutions in autonomous robotics and path planning. This chapter underscored the gaps in current approaches and the opportunity for innovative optimization strategies, especially in environments like brown-field warehouses, where challenges such as disorganization and uneven terrain present significant obstacles to automation.

Chapter 3 marked the technical core of the thesis, focusing on the mathematical and geometric principles behind the proposed solution. The exploration of splines in path planning, combined with the geometric division of warehouse stations into transition zones, highlighted the need for precision and flexibility in near-field navigation. Through a detailed discussion of path discrimination and optimization methods, this chapter demonstrated how smart algorithms can enable autonomous vehicles to plan and execute efficient routes while avoiding obstacles.

Finally, Chapter 4 presented the practical implementation of these ideas in the RACK framework and simulation system, detailing the tests conducted on autonomous forklifts and the results obtained. The successful trials showcased the efficacy of the optimized local path planning approach, proving that the developed solution is not only theoretically sound but also practically applicable in real-world scenarios.

In conclusion, this thesis has demonstrated that the desired optimizations can be achieved by implementing less sophisticated path planning techniques and without the need to implement overkill solutions like AI-based. The proposed approach contributes to the growing body of knowledge in autonomous robotics and intralogistics, offering a solution that enhances safety, efficiency, and predictability which opens the door for customers and potential customers to trust the presence of the autonomous forklifts in complex intralogistics environments with the european standards.
